(eds).

Proceedings of the 13th International Conference on Educational Data Mining
Anna N. Rafferty, Jacob Whitehill, Cristobal Romero, Violetta Cavalli-Sforza (eds).
July 10th – 13th 2020
ISBN: 978-1-7336736-1-7

PREFACE

For this 13th iteration of the International Conference on Educational Data Mining (EDM 2020), the conference was held completely online. EDM is organized under the auspices of the International Educational Data Mining Society in Montreal, Canada. The conference, held July 10th through 13th, 2020, follows twelve previous editions (Montreal 2019, Buffalo 2018, Wuhan 2017, Raleigh 2016, Madrid 2015, London 2014, Memphis 2013, Chania 2012, Eindhoven 2011, Pittsburgh 2010, Cordoba 2009, and Montreal 2008).

The official theme of this year’s conference is Improving Learning Outcomes for All Learners. The theme comprises two parts: (1) Identifying actionable learning or teaching strategies that can be used to *improve* learning outcomes, not just predict them. (2) Using EDM to promote more *equitable* learning across diverse groups of learners, and to benefit underserved communities in particular. This year’s conference features three invited talks: Alina von Davier, Chief Officer at ACTNNext; Abelardo Pardo, Professor and Dean of Programs (Engineering), at UniSA STEM, University of South Australia; and Kobi Gal, Associate Professor at the Department of Software and Information Systems Engineering at Ben-Gurion University of the Negev, and Reader at the School of Informatics at the University of Edinburgh.

Building on the policy started in 2019, EDM 2020 used a double-blind review process. The conference’s Program Committee was also significantly expanded compared to 2019 in an effort to reduce the average load per reviewer and thereby increase the quality of reviews. This year we received a total of 98 full-paper submissions and 64 short-paper submissions. From the full-paper submissions, 30.6% were accepted as full papers, 16.3% were accepted as short papers, and 15.3% were accepted as posters. From the short-paper submissions, 21.9% were accepted as short papers and 23.4% were accepted as posters.

Review & Decision Processes: For transparency and possible benefit of future EDM conferences, we are providing a detailed description of the paper review and decision processes for the Full and Short paper tracks at EDM 2020:

1. After all papers were submitted, the Program Committee (PC) and Senior Program Committee (SPC) members bid on which papers they would like to review.
2. If committee members did not bid on papers after several reminders, bids were entered for them. This was done automatically via the EasyChair conference management system if the committee members had entered topics. Otherwise, one of the Program Chairs entered topics for the committee members based on examining publications in their Google Scholar profile; these topics were then used to automatically create bids.
3. Given the PC and SPC bids, the Program Chairs assigned papers to reviewers using EasyChair’s automatic assignment option. This assignment maximizes the total score of the assignment, with high weight on matches where the bid was a “yes”, medium weight on matches where the bid was a “maybe”, and low weight on matches where the bid was a “no”. Each paper was assigned to one SPC member and two PC members. Each PC member received at most 5 papers, and each SPC member received at most 4 papers. The automated reviewing assignment was manually checked to ensure fairness to reviewers in being primarily assigned papers for which they had entered positive bids, fairness to papers in being primarily assigned reviewers who had bid positively on that paper, and that automatic conflict detection had accurately detected conflicts. One set of changes involving three papers was made based on this

manual check due to assigning a paper to a reviewer that she had bid “no” on and that did not match her stated topics of expertise. In a separate change, another swap was made to prevent a reviewer from being assigned their own paper, as the authorship and reviewer information on EasyChair did not exactly match.

4. In an effort to increase the mean and decrease the variance in review quality, the Program Chairs defined reviewing guidelines, both for the PC and the SPC. These guidelines were posted to the EDM 2020 website and also linked in emails sent to reviewers.
5. At the end of the review period, the Program Chairs identified papers that received fewer than 3 reviews, as well as papers whose reviews were clearly lacking (e.g., just 1-2 sentences). Emergency reviewers (including the Program Chairs) were identified, and papers were assigned to them.
6. The Program Chairs examined the meta-reviews and acceptance/rejection recommendations for all papers. For any papers lacking a meta-review, the Program Chairs read the reviews and the paper, wrote a meta-review, and arrived at a recommendation for acceptance/rejection.
7. Papers were ranked by their unweighted average review scores. The Program Chairs then manually identified and examined papers in “critical regions” of the ranking in which there was large variance in the meta-reviewers’ decision recommendations (Accept as Full, Accept as Short, Accept as Poster, Reject). The goal here was to ensure that, in the opinions of both Program Chairs, all papers accepted as either Full or Short exhibited sufficient rigor for publication as such. When in doubt, the more conservative outcome (i.e., Accept as Short rather than Full, or Accept as Poster rather than Short) was chosen. In particular:
 - (a) For the Full paper track, the following range was calculated: Let m_f be the lowest score of any paper recommended by its meta-reviewer for “Accept as full”, and let n_s be the highest score of any paper recommended by its meta-reviewer for “Accept as short”. For any paper recommended for “Accept as full” whose score was in $[m_f, n_s]$, the Program Chairs discussed the paper and decided jointly whether to Accept as Full or Short. This deliberation focused on the question: “Do the reviewers point out important methodological or other fundamental problems that could significantly threaten validity?”
 - (b) The analogous process (both for papers submitted as Full, and for papers submitted as Short) was applied to papers whose unweighted average review scores were in the range $[m_s, n_p]$, where m_s is the lowest score of any paper recommended for Accept as Short and n_p is the highest score of any paper recommended for Accept as Poster.
 - (c) All other papers – i.e., those whose unweighted average review scores were outside of the ranges described above – were accepted/rejected according to the recommendation of their assigned meta-reviewer.

During all aspects of both the Review and Decision processes, no Program Chair examined or handled any paper on which he/she was a co-author; any such paper was seen and handled exclusively by the other Chair to avoid a conflict of interest. (No papers were co-authored by both Program Chairs.)

Note that papers submitted to the Industry, Doctoral Consortium, Poster/Demo, and Workshop components of EDM 2020 had their own reviewing processes that were defined by the corresponding chairs in consultation with the Program Chairs. Papers published in the Poster/Demo track are the union of those submitted & accepted as Posters/Demos, and those submitted to either the Full

or Short tracks that were accepted as Posters.

Posters/Demos: In addition to the Full or Short paper submissions that were accepted as posters mentioned above, there was a dedicated Poster/Demo track to which papers could be submitted directly. This track accepted 14 contributions out of 17 submissions.

JEDM: Together with the Journal of Educational Data Mining (JEDM), the EDM 2020 conference held a JEDM Track that provides researchers a venue to deliver more substantial mature work than is possible in a conference proceeding and to present their work to a live audience. The papers submitted to this track followed the JEDM peer review process. Two JEDM papers are featured in the conference’s program.

Industry: The main conference invited contributions to an Industry Track in addition to the main track. The EDM 2020 Industry Track received 6 submissions of which 5 were accepted.

Doctoral Consortium: The EDM conference continues its tradition of providing opportunities for young researchers to present their work and receive feedback from their peers and senior researchers. The doctoral consortium this year features 19 such presentations.

Paper Topics: In terms of topics of all submitted papers, the table below lists the most popular keywords associated with papers as selected by the authors themselves from a keyword list created by the Program Chairs:

Topic	# Paper Submissions
Log files/transaction logs	105
Modeling student learning	72
Other supervised machine learning	63
Post-secondary/College	55
Assessment	53
Intelligent tutoring systems	49
Natural language	48
Neural networks & deep learning	42
Unsupervised learning and clustering methods	41
Supporting teachers	33
MOOCs	30
K-12 classrooms	30
Building frameworks for EDM	30
Predicting attrition/drop-out	24
Data visualization methods	19
Informal learning environments	17
Collaborative learning	17
Images/video	17
Adult learning	17
Game-based learning	16
Multimodal analytics	15
Topic modeling	14
Closing the loop between research and practice	14
Advancing theories of learning	14
Building domain knowledge models	13
Bayesian models	12
Equity and fairness in EDM	10
Lab-based experiments	10
Socio-emotional learning and affect	8
Physiological sensors	8
Crowdsourcing	7
Social network analysis	6
Lifelong learning	6
Reinforcement learning	5
Treatment effect estimation	3
Causal inference techniques	2
Issues of Accessibility in Learning	1
Audio	1

Test of Time Award: Following in the footsteps of last year’s conference, EDM 2020 also includes an invited talk by the authors of the 2019 winner of the EDM Test of Time Award. This year’s talk is delivered by Ryan Baker and Kalina Yacef.

Workshops & Tutorials: In addition to the main program, there are workshops and tutorials on: Causal Inference in Educational Data Mining; Educational Data for Mining in Computer Science Education (CSDM); FATED: Fairness, Accountability, and Transparency in Educational Data (Mining); Reproducibility and Replication of Analytic Methods with LearnSphere; The Learner Data Institute: Big Data, Research Challenges, & Science Convergence in Educational Data Science; and An Introduction to Neural Networks.

Coronavirus: This year’s conference was originally arranged to take place in Ifrane, Morocco. Due to the SARS-CoV-2 (coronavirus) epidemic, EDM 2020, as well as most other academic conferences in 2020, had to be changed to a purely online format. This presented some difficulties, especially of how to engage and encourage interaction among participants using just Zoom and other online tools rather than face-to-face meetings. However, it also significantly reduced the costs of conducting and attending the conference since physical meeting spaces, air travel, and on-site lodging were no longer necessary – and this arguably increased our conference’s accessibility. To facilitate efficient transmission of presentations, especially given that not everyone’s Internet connection could be guaranteed to be stable, we required all paper presenters to pre-record their presentation as a video and then to host it on YouTube. Moreover, we asked that all presenters enable closed-captioning (CC), for the benefit of deaf people and those hard of hearing, as well as non-native English speakers who prefer to read than to listen to audio.

Thanks: We thank ACTNext as a sponsor of EDM 2020 for its generous support, especially during this financially difficult time of the coronavirus. We are also grateful to the individual conference chairs, the senior program committee, regular program committee members, sub-reviewers, emergency reviewers, and IEDMS board members, without whose expert input and hard work this conference would not be possible. Finally, we thank the entire organizing team and all authors who submitted their work to EDM 2020.

<i>Anna N. Rafferty</i>	Carleton College, USA	Program Chair
<i>Jacob Whitehill</i>	Worcester Polytechnic Institute, USA	Program Chair
<i>Cristobal Romero</i>	University of Cordoba, Spain,	General Chair
<i>Violetta Cavalli-Sforza</i>	Al Akhawayn University in Ifrane, Morocco	General Chair

June 23rd, 2020

ORGANIZING COMMITTEE

General Chairs: Cristobal Romero (University of Cordoba, Spain) and Violetta Cavalli-Sforza (Al Akhawayn University in Ifrane, Morocco)

Program Chairs: Anna N. Rafferty (Carleton College, USA) and Jacob Whitehill (Worcester Polytechnic Institute, USA)

Workshop & Tutorial Chairs: François Bouchet (Sorbonne University, France) and Vanda Lúengo (Sorbonne Université, France)

Industry Track Chairs: Shonte Stephenson (BrightBytes, USA) and Nigel Bosch (University of Illinois at Urbana-Champaign, USA)

Doctoral Consortium Chairs: Neil Heffernan (Worcester Polytechnic Institute, USA) and Carol Forsyth (Educational Testing Service, USA)

JEDM Track Chairs: Michel Desmarais (Polytechnique Montreal, Canada) and Agathe Merceron (Beuth University of Applied Sciences, Germany)

Poster & Demo Track Chairs: Juan Alfonso Lara Torralbo (UDIMA, Spain) and Rebeca Cerezo (University of Oviedo, Spain)

Publication/Proceedings Chairs: Pedro J. Muñoz-Merino (Universidad Carlos III de Madrid, Spain) and Alexandra I. Cristea (Durham University, UK)

Sponsorship Chairs: Piotr Mitros (ETS, USA) and Olga C. Santos (UNED, Spain)

Publicity/Social Media Chair: Miguel Á. Conde (University of Leon, Spain)

Web Chair: Paul Salvador Inventado (California State University, USA).

IEDMS Officers:

Kenneth Koedinger,	President	Carnegie Mellon University, USA
Mingyu Feng,	Treasurer	WestEd, USA

IEDMS Board of Directors:

Rakesh Agrawal	Data Insights Laboratories, USA
Ryan Baker	University of Pennsylvania, USA
Tiffany Barnes	North Carolina State University, USA
Michel Desmarais	Ecole Polytechnique de Montreal, Canada
Sidney D'Mello	University of Colorado Boulder, USA
Luc Paquette	University of Illinois Urbana-Champaign, USA
John Stamper	Carnegie Mellon University, USA
Mykola Pechenizkiy	Eindhoven University of Technology, Netherlands
Kalina Yacef	University of Sydney, Australia

SPONSORS

Best Paper Selection

Nominees for Best Paper Award were all full papers with an average review score greater than 2, where the average review score was weighted by the reviewer’s self-reported confidence. These papers were sent to and evaluated by all the board members of the International Educational Data Mining Society (IEDMS) who were not co-authors of one of the nominated papers. These board members selected the recipient of the Best Paper and Best Student Paper awards.

Best Paper Nominees: The nominated papers were:

1. Mike Wu, Richard Davis, Benjamin Domingue, Chris Piech and Noah Goodman. “Variational Item Response Theory: Fast, Accurate, and Expressive.”
2. Nigel Bosch, Wes Crues, Najmuddin Shaik and Luc Paquette. “Hello, [REDACTED]’: Protecting Student Privacy in Analyses of Online Discussion Forums.”
3. Adam Sales and John Pane. “The effect of teachers reassigning students to new Cognitive Tutor sections.”
4. Nathan Henderson, Vikram Kumara, Wookhee Min, Bradford Mott, Ziwei Wu, Danielle Boulden, Trudi Lord, Frieda Reichsman, Chad Dorsey, Eric Wiebe and James Lester. “Enhancing Student Competency Models for Game-Based Learning with a Hybrid Stealth Assessment Framework.”

Note that papers #1 and #4 above were also nominated for the **Best Student Paper Award**.

Online Collaborative Student Group Learning

Keynote

Kobi Gal
Ben-Gurion University of the Negev, and University of Edinburgh

Abstract

Collaborative student learning has been shown to lead to significant academic benefits among students, and to improved social skills that are critical for the workforce, such as communication and teamwork. However, these benefits were limited to small face-to-face groups and required the support of human experts who actively monitored and guided the group's learning.

Technological advances now enable globally dispersed teams to collaborate online, from Q&A forums to virtual laboratories. Augmenting these settings with AI technology can scale up the benefits of collaborative group learning to online groups.

I will describe challenges to EDM research for supporting this new type of online teamwork, as well as opportunities for combining AI and learning analytics towards supporting students' learning and teachers' understanding of how students learn.

Biography

Kobi Gal is an Associate Professor at the Department of Software and Information Systems Engineering at Ben-Gurion University of the Negev, and Reader at the School of Informatics at the University of Edinburgh. Gal's work combines artificial intelligence algorithms with educational technology towards supporting students in their learning and teachers in their understanding how students learn. He has published widely in highly refereed venues on topics ranging from artificial intelligence to the learning and cognitive sciences.

Gal is the recipient of the Wolf foundation's 2013 Krill prize for young Israeli scientists, a Marie Curie International fellowship, and a three-time recipient of Harvard University's outstanding teacher award. He has received best paper awards at ACM Conference on User Modeling Adaptation and Personalization 2019 (UMAP-19), ACM conference on Economics and Computation 2016 (EC-16), Educational Data Mining 2014 (EDM-14). Gal is the acting president of the Israeli Association for Artificial Intelligence.

Contextualising Data Mining within Educational Experiences

Keynote

Abelardo Pardo
University of South Australia

Abstract

The use of technology to mediate learning experiences provides an unprecedented amount of information that can be used to increase our understanding and improve the overall quality of those experiences. However, learning in general is strongly mediated by a very rich set of contextual factors. The two crucial steps to translate data into knowledge, sensemaking and deriving actions, are especially sensitive to these factors, and as such, need to be carefully considered to maximise positive outcomes. Areas such as personalisation are highly sensitive to the context in which each learner is engaged in an experience. Data-intensive techniques need to factor in these elements and assure learners are not adversely affected by situations ignored or inadequately handled by algorithms. This talk aims to explore how data mining applications can be properly situated to have a positive impact in specific aspects such as learning outcomes or connecting insights derived from data analysis with actions.

Biography

Abelardo Pardo is Professor and Dean of Programs (Engineering), at UniSA STEM, University of South Australia. His research interests include the design and deployment of technology to increase the understanding and improve digital learning experiences. More specifically, his work examines the areas of learning analytics, personalized active learning, and technology for student support.

He is the author of over 150 research papers in scholarly journals and international conferences in the area of educational technology and engineering education. He is currently member of the executive board and president of the Society for Learning Analytics Research (SoLAR).

An AI-enabled Ecosystem for Learning & Assessment

Keynote

Alina von Davier
ACTNext

Abstract

AI-based tools, integrative technology and standards for various purposes in education have undergone significant development in the past few years. The vision is to build towards processes and/or parts thereof that are automatic and seamlessly integrated. In this presentation I will illustrate the architecture of a fluid infrastructure to effectively support learning and assessment systems. Each component is designed within a computational framework (AI blended with psychometrics) and each connection relies on construct taxonomy, database alignment, data exchange standards, and APIs.

I will describe a key AI-based content generator, Sphinx, developed at ACTNext. I'll use the ACTNext Educational Companion App as an example of how the pieces come together. Last but not least, I'll show how voice-based interface can be integrated within the versatile systems. The work has been conducted with an interdisciplinary team at ACTNEXT.

Biography

Alina von Davier, PhD., is the Chief Officer at ACTNext, a multidisciplinary innovation unit that is part of ACT and was founded in 2016. Her team is comprised of experts in fields ranging from psychometrics and learning sciences to software development, and artificial intelligence (AI) & machine learning (ML). Von Davier and her team operate at the forefront of Computational Psychometrics, an emerging interdisciplinary field concerned with the application of theoretical and data-driven computational methods and statistical modeling of multimodal, large scale/high dimensional learning and assessment data. Prior to leading ACTNext, von Davier was a senior research director at Educational Testing Service (ETS) where she led the Computational Psychometrics Research Center. Previously, she led the Center for Psychometrics for International Tests, where she was responsible for both the psychometrics in support of international tests, TOEFL[®] and TOEIC[®], and the scores reported to millions of test takers annually.

Von Davier is currently an adjunct professor at Fordham University and the president of the International Association of Computerized Adaptive Testing (IACAT). She currently serves on the board of directors for the Association of Test Publishers (ATP), and she is also a member of the board of directors for Smart Sparrow and of the advisory board for Duolingo.

When is Deep Learning the Best Approach to Knowledge Tracing?

Theophile Gervet, Ken Koedinger, Jeff Schneider and Tom Mitchell
Carnegie Mellon University

Abstract

Intelligent tutoring systems (ITSs) teach skills using learning-by-doing principles and provide learners with individualized feedback and materials adapted to their level of understanding. Given a learner's history of past interactions with an ITS, a learner performance model estimates the current state of a learner's knowledge and predicts her future performance. The advent of increasingly large scale datasets has turned deep learning models for learner performance prediction into competitive alternatives to classical Markov process and logistic regression models. In an extensive empirical comparison on nine real-world datasets, we ask which approach makes the most accurate predictions, in what conditions. Logistic regression – with the right set of features – leads on datasets of moderate size or containing or containing a very large number of interactions per student, whereas Deep Knowledge Tracing leads on datasets of large size or where precise temporal information matters most. Markov process methods, like Bayesian Knowledge Tracing, lag behind other approaches. We follow this analysis with ablation studies to determine what components of leading algorithms explain their performance and a discussion of model calibration (reliability), which is crucial for downstream applications of learner performance prediction models.

Abstract

The growing use of machine learning for the data-driven study of social issues and the implementation of data-driven decision processes has required researchers to re-examine the often implicit assumption that data-driven models are neutral and free of biases. The careful examination of machine-learned models has identified examples of how existing biases can inadvertently be perpetuated in field such as criminal justice – where failing to account for racial prejudices in the prediction of recidivism can perpetuate or exasperate them – and natural language processing – where algorithms trained on human languages corpora have been shown to reproduce strong biases in gendered descriptions. These examples highlight the importance of thinking about how biases might impact the study of educational data and how data-driven models used in educational context may perpetuate inequalities. To understand this question, we ask whether and how demographic information, including age, educational-level, gender, race/ethnicity, socio-economic status (SES) and geographical location, is used in Educational Data Mining (EDM) research. Specifically, we conduct a systematic survey of the last five years of EDM publications that investigates whether and how demographic information about the students is reported in EDM research and how this information is used to 1) investigate issues related to demographics, 2) use the information as input features for data-driven analyses or 3) to test and validate models. This survey shows that, although a majority of publication reported at least one category of demographic information, the frequency of reporting for different categories of demographic information is very uneven (ranging from 5% to 59%) and only 15% of publications used demographic information in their analyses.

ABSTRACT

Educational software data promises unique insights into students' study behaviors and drivers of success. While much work has been dedicated to performance prediction in massive open online courses, it is unclear if the same methods can be applied to blended courses and a deeper understanding of student strategies is often missing. We use pattern mining and models borrowed from Natural Language Processing (NLP) to understand student interactions and extract frequent strategies from a blended college course. Fine-grained clickstream data is collected through Diderot, a non-commercial educational support system that spans a wide range of functionalities. We find that interaction patterns differ considerably based on the assessment type students are preparing for, and many of the extracted features can be used for reliable performance prediction. Our results suggest that the proposed hybrid NLP methods can provide valuable insights even in the low-data setting of blended courses given enough data granularity.

Keywords

Student Strategies, Blended Courses, hybrid NLP methods

1. INTRODUCTION

Data collected through educational software systems can provide promising starting points to address hard questions rooted in the learning sciences. Modern education relies increasingly on these systems to assist teaching and grading, manage learning content, provide discussion boards, facilitate group work, or replace the traditional class room setting altogether. While blended courses revolve around the traditional class room setting accompanied by task-specific software support, Massive Open Online Courses (MOOCs) are usually entirely virtual and often involve video lectures and hundreds to thousands of students in a single course. Almost by design, these systems come with unprecedented opportunities for large scale data collection on students' study habits, content exposure and learning trajectories.

Much of the previous research effort has been directed towards performance prediction with the overall rationale that reliable estimation of students' grades and dropout probability at early course stages can be used to devise Early Warning Systems (EWSs) [e.g. 31, 19, 30, 7]. Despite considerable success in this area, many performance prediction models suffer from a list of shortcomings. Prior work on performance prediction from student online activity data has predominantly focused on MOOCs [e.g. 8, 28, 25], and it is unclear if the same methods can be applied to blended courses [3]. In most blended courses, some of the learning activity takes place offline and cannot be tracked which leads to relatively shallow data on only fragments of courses. In addition, many of the features that can be derived are simple and coarse summary statistics of students' online activity data, e.g. counts of clicks or logins, that only have a limited capacity to reflect the often complex strategies students take when interacting with course material.

A detailed understanding of how students interact with educational systems and the strategies they take is crucial for reliable performance prediction. We thus seek to understand how students approach learning in blended courses based on the second half of a sophomore level college course in computer science. Our data is drawn from Diderot, a non-commercial educational software system developed at Carnegie Mellon University which spans functions for virtually all course components outside of face-to-face class and recitation times, and thereby allows us to overcome many of the challenges that are generally faced when mining blended courses. Despite evident similarities, there are several important characteristics which differentiate our blended learning setting from the study of MOOCs. Most importantly, our data spans relatively few students and student actions which constitutes a challenge for many of the previously proposed methods. In addition, we have access to data that is unique to in-person classes such as individual attendance, and the nature of our activity data facilitates contextualization of student behavior which promises to increase the interpretability of downstream prediction models.

In this paper, we place a dual focus on methodology and educational insights. On the one hand, we propose new modeling pipelines based on ideas from natural language processing that work well in the low-data setting of blended courses. On the other hand, we apply both new and existing methods to Diderot data and gain valuable insights into student behavior while addressing the following research questions:

Nil-Jana Akpinar, Aaditya Ramdas and Umut Acar "Analyzing Student Strategies In Blended Courses Using Clickstream Data" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 6 - 17

- RQ1** How do students interact with course material, and what are frequent strategies they take?
- RQ2** How do students use these strategies for homework solving as compared to exam preparation?
- RQ3** Are student strategies indicative of grade outcomes?

The remainder of this paper is outlined as follows. We discuss related work in Section 2, and proceed to give some context for the data in Section 3. Section 4 describes our methods including the preprocessing of clickstream data, and we discuss our results in Section 5. Finally, conclusions are drawn in Section 6.

2. RELATED WORK

2.1 Analysis Of Online Student Behavior

Raw data from educational software systems often comes in the form of time-stamped student actions with an array of suitable identifiers. Evidence for correlations between activity log-based features and performance outcomes are plentiful. Many of the commonly discussed features revolve around simple summary statistics such as counts of certain types of actions, and have been shown to be indicative of students' success particularly in MOOCs. Recent lines of research find links between general course completion in MOOCs and the number of watched videos [39, 9], the number of question answer attempts [9], and the time spent on assignments [4]. Similar results have been observed for blended courses but are much scarcer [40, 16]. In [16], the authors analyze sequences of transitions between different online platforms in two undergraduate level college courses. Their study finds that, although students are generally more likely to stay on the same platform in a study session, high achieving students transition more often and are more likely to use the discussion board. In many cases, the limited amount of data in blended courses is problematic and can lead to complications such as zero-inflated count variables.

A major shortcoming of count-based methods is their failure to leverage the sequential structure of students' interactions with educational software systems. Both the order and the time difference between actions promise to carry valuable information that can be taken into consideration when relying on sequence based methods instead. In this work, we propose a pipeline for analyzing student online behavior based on session study sequences. While the order of actions is taken into account explicitly, time differences help us to derive reliable study sessions.

2.2 Study Sessions

Sequence-based approaches to processing online student activity data group student actions into smaller sessions. In the case of click actions, these sequences are generally referred to as clickstreams. The goal when breaking a flow of actions into session clickstreams is to maintain some notion of interpretability, i.e. to devise meaningful study sessions. While this appears to be easy in some cases, it is generally non-trivial to find automated cut-offs rules that find sensible representations of study sessions for a large and diverse set of clickstreams at once.

Previous research suggests several different strategies to split clickstreams. The authors of [8] choose fixed duration time frames to group student actions from a several months long MOOC. The researchers decide for durations between one day and one month and show some success in the downstream prediction of student achievements with their choices. Similar fixed durations are used in [2]. Another popular splitting strategy is based on time-out thresholds where a new sub-session is started when no action was performed in a predefined time window [32, 5, 36, 12, 13]. The authors of other studies go one step further and combine the approaches by first, splitting at a fixed duration cut-off and second, at data-driven timeout thresholds of 15 minutes for 'study sessions' and 40 minutes for 'browser sessions' [16]. Similar data-driven approaches are pursued in [45, 40]. Other common heuristics include splitting at navigational criteria such as reloading of the course page [26].

On a high level, the problem of devising meaningful sub-sessions is closely related to the problem of time-at-task estimation in web-usage mining. Ideally, study sessions reflect time periods in which students interact with the material without any major breaks or distractions. There is a rich body of literature on time at task estimation that suggests that there is no one-fits-all solution to finding suitable time windows to split activity streams at [e.g. 26, 6, 11]. Previous research suggests that the exact splitting heuristic can have a significant effect on overall model fit, model significance, and even interpretation of findings in the downstream modeling tasks [26]. In [26], the authors explore the effect of 15 different time-at-task estimation procedures on five different models of student performance. Overall, the authors conclude that there is no universally best method and recommend a mixture of existing methods including data-driven components. Following this suggestion, we employ a multi-step splitting procedure including navigational criteria, data-driven time-out thresholds, and separation of assessment weeks inspired by the procedure in [16].

2.3 Sequence Analysis

Different methods have been proposed to process sequence-type student action data dependent on the amount of data, the length of sequences, and the goal at hand. Several lines of research rely on Markov chains and hidden Markov models which lend themselves well to visualization of sequences, but can make quantification of group differences in outcomes challenging [15, 14, 20]. Another commonly used class of methods is clustering of activity sequences [13, 23, 17]. Using data from three large MOOCs, the authors of [23] draw on simple k -means clustering of sequences of interactions with video lectures and assessments and observe four high-level student trajectories: completing assessments, auditing the course, disengaging after a while, and sampling content. In order to cluster the sequences, the authors rely on a numerical translation of student actions. The authors of [13] cluster and visualize students' interactions with a college math environment, and instead rely on Levenshtein distance to measure the distance between sequences. Some works combine Markov models and clustering to account for the randomness introduced by the Markov models and report more robust results [41, 27, 24].

Although the described methods allow for a relatively easy

grouping of sequences, interpretation of clusters can be non-obvious. One way to address this problem is to deliberately focus on finding relevant sub-parts of action sequences. Methods based on this goal can be summarized under the term pattern mining, and are both wide-spread and diverse. A relatively recent approach is given by differential pattern mining which focuses on automatically extracting patterns that are both above a certain threshold in frequency, and sufficiently different among groups of interest (e.g. high and low achieving students) [22, 21]. Other lines of research rely on more traditional data mining techniques [18, 35], or extraction of n -grams, i.e. sub-sequences of n consecutive actions [8, 33, 44, 37]. The authors of [33] use a multi-step procedure to extract frequent n -grams that are subsequently used to identify different strategies in a collaborative interactive tabletop game. Part of our analysis is based on a similar approach to extract frequent behavioral patterns, and combines ideas of n -gram extraction and clustering to get more robust results.

A different class of promising methods is rooted in Natural Language Processing (NLP). Hybrid language models lend themselves well to the sequential structure of education data, and their use for student activity sequences has lead to some success in retrieving patterns and creating new visualizations. The underlying idea is that, given sufficiently fine-grained data, students' sequential actions resemble words building sentences and can be attributed some 'semantic meaning'. The NLP toolbox has not yet been explored fully, but some attempts to using language models for educational data are noteworthy and relevant for the context of our work. The authors of [44] use topical n -gram models to automatically extract 'topics' in the form of frequent patterns from clickstreams. In [37], the authors train a skip-gram neural network to receive a structure preserving vector embedding of the types of clicks student can make. After standard dimensionality reduction, the researchers are able to provide a new kind of visualization of students' trajectories through the course. Since modern NLP models generally require large amounts of granular training data, work relying on these models has exclusively focused on MOOCs so far. In this study, we draw on Latent Dirichlet Allocation (LDA) in order to automatically extract frequent patterns and compare derived student strategies against the results of a more traditional n -gram pipeline. In some sense, LDA is similar to the ideas proposed by [44] but requires less training data which renders it particularly useful for blended courses. In addition, we use an adapted form of the skip-gram model proposed by [37] in order to explore the context of student actions in our data. To the best of our knowledge, this is one of the first works to employ NLP methods for analysis of blended courses.

3. DATA

3.1 Data Context: Diderot

The data this study builds on was collected through the educational software system Diderot. Diderot is a cloud-based course support system commonly used to assist undergraduate and graduate level college courses. The system spans a wide range of functionalities including sharing of lecture notes, a discussion board (called post office), in-class attendance polls, homework submission, and automatic code grading. This bandwidth usually renders the use of addi-

Figure 1: Histogram of the number of clicks per student. We observe 138,960 clicks spread between 164 students (top). Number of clicks over observation period with assessment deadlines highlighted (middle). Kernel density estimates for log-distribution of waiting times between clicks dependent on type of last click after splitting at assessment weeks and Load course actions. Final cut-offs at 5 and 60 minutes are indicated by vertical lines (bottom).

tional outside technological course support unnecessary. In turn, the student usage data collected from Diderot can give an almost comprehensive view on students' course participation outside of face-to-face class times.

When it comes to sharing of lecture notes, Diderot takes a more granular and interactive approach as compared to traditional learning management systems. Content is split into small sub-entities (called atoms) which are displayed in a linear fashion following the outline of a chapter. Atoms are highly interactive and come with a variety of clickable icons that allow students to take notes, bookmark, follow, or like atoms, and, in particular, to ask questions concerning their content. Discussions about course material that are sparked in this way are visually attached to the respective atom, allowing other students to submit comments. This setup results in much richer data on interactions with lecture notes

than we can expect from PDF formatted lecture material.

Most student usage data from Diderot is presented by individual, time-stamped click actions that come with various identifiers coding the exact type, user, and location of the interaction. In turn, the activity data can be broadly separated into navigation (e.g. `Load course`, `Click link`, `Search`), discussion (e.g. `Go to post office`, `Create post`), and behaviors (e.g. `Like atom`, `Follow post`).

3.2 Data Description And Exploration

Our data is drawn from the second half of a large sophomore-level computer science course taught at Carnegie Mellon University in spring 2019. Since data is not available for the first part of the course due to initial technical difficulties, we exclude all students who dropped the course throughout the semester. One additional student was excluded based on inflated click patterns which suggested an attempt at automatically scraping content. Along with the click data, we rely on performance information measured by homework and exam grades, as well as student-level lecture and recitation attendance logs. All data is collected through Diderot and matched based on anonymous student identifiers. A summary of the click data over the seven week observation period is displayed in Figure 1.

Types of clicks. At finest granularity, Diderot allows for several tens of thousands distinct click actions within a single course since every individual click is associated to a fully specified object and activity. However for the sake of analysis, we group clicks into different types where the appropriate level of granularity is non-obvious. We aggregate clicks based on the type of object they refer to as well as the activity performed. In order to maintain interpretability, this aggregation is performed separately in each sub-part of the course given by lecture notes, homework material, recitation notes, a library documentation (which is comprised of coding references), and practice exams. This leaves us with 37 different click types, the most common of which are summarized in Table 1.

Grades and types of assessment weeks. Performance outcomes are measured by percentage grades in five homeworks and two exams (a midterm and final exam) that fall into the observation period. This naturally divides the data into seven assessment weeks with a deadline for a homework problem set or exam at the end of each period. Deadlines are approximately evenly spaced with only one extended homework period of 11 days after the midterm exam (which also spans over a four day spring holiday), followed by a shorter homework period of only 5 days. We take interest in relating students’ study behavior to two distinct outcome variables: (1) The type of the assessment week, i.e. homework deadline or exam, and (2) the percentage grade students received in the respective assessment. As depicted in Figure 1, there are visible spikes of increased activity before the assessment week deadlines especially before the two exams. In addition, we note that the distribution of grades appears notably different between homeworks and exams which is confirmed by a two-sample Kolmogorov-Smirnov test ($p < 0.001$). While the distribution of exam grades is approximately bell-shaped with heavy tails and a slight left-skew, i.e. more particularly high scores than particularly low scores, the homework grade

Table 1: Summary of the most frequent click types.

Click type	Count	Share
View chapter in lecture notes	24,420	17.57 %
View general post	21,555	15.51 %
Load course	19,677	14.16 %
View post office	16,231	11.68 %
View atom post	15,468	11.13 %
View homework atom	7,888	5.68 %

distribution is left-skewed with additional modes at 0 and 100. This difference in distributions is unsurprising as exams are generally graded on a curve and cannot be skipped by students, while homeworks allow for more variability.

Class attendance. Attendance in lecture and recitation sessions was taken with Diderot polls. If a student participated in the poll, which was generally only open for a few minutes, it was assumed that they attended the session. We treat attendance in lectures and recitations separately and aggregate the binary information on an assessment week basis by taking the mean. In turn, student’s attendance scores lie between 0 and 1 with the exception of the final exam week which is not associated to any contact class time.

4. METHODS

4.1 Session Clickstreams

In raw form, each student is associated with a single clickstream which consists of ordered click actions over the whole observed time period. We employ a multi-step procedure to split this data into more meaningful study sessions. First, we divide the clickstreams based on assessment weeks. Second, we split the resulting sub-clickstreams each time a `Load course` action is recorded, and last, we choose a data-driven timeout threshold to further break up the resulting sequences.

In order to find a suitable timeout threshold, we employ a technique similar to [16] and examine the distribution of time differences in the sub-sequences. We find that the distribution of waiting times supports a wide range but is rapidly decaying. While 75 % of clicks are made within 2.81 minutes or less, a small subset of clicks has time differences of up to 7 days. Figure 1 shows kernel density estimates of log-transformed minutes until the next click within the sub-clickstreams obtained after the second step of our procedure. Different estimates are obtained for distinct categories of actions. While the logarithmic distribution of post-related and miscellaneous clicks is unimodal with the majority of follow-up clicks made within one minute, the distribution for clicks related to homework and lecture notes has an additional mode at about 5-10 minutes. This disparity is unsurprising given that most actions can be expected to be short, while reading through lecture notes or homeworks can be a more lengthy process. In order to preserve both types of sessions, we separate clickstreams at a 60 minutes threshold if the last action was loading of lecture notes or homework related content, and at 5 minutes otherwise. As a result, we obtain a total of total of 35,703 session clickstreams where each clickstream has between one and 115 clicks with mean

Figure 2: Skip-gram neural network. The hidden layer linearly transforms one-hot encoded inputs while the softmax output layer approximates the probability that each given click type appears in the same context as the input click. After training, the weights of the hidden layer provide a structure preserving embedding of click types.

of 3.98 clicks and standard deviation of 6.23; 75% of session clickstreams have at most 4 clicks.

4.2 Context Of Click Types

We explore the contexts in which different types of clicks are made in order to gain some understanding of how students generally use the course support system. This is crucial since Diderot is a fully integrated interactive platform that allows the same type of click in contexts that can have different interpretations. Inspired by [37], we tackle this problem by devising a structure-preserving embedding of the click types into a real-valued vector space, i.e. each click type is mapped onto a vector such that click types that appear in the same contexts or are interchangeable are close to each other. This type of embedding can be obtained from a skip-gram model which is a common supervised two layer neural network model often used for language type data (see Figure 2).

Training data for the model is build by extracting pairs of neighboring click types from the session clickstreams. More concretely, each input click is paired with each click appearing within some index in the same clickstream. Both the window size and the number of hidden units are important hyperparameters. Since most of our clicks are short and we seek an embedding of only 37 clicktypes, we explore small values for both parameters, i.e. window sizes in $\{1, 2\}$ and embedding sizes in $\{3, 4\}$. After this small grid search, we only retain the model with the lowest average training loss in the last 2000 training steps. In order to speed up training, we rely on mean noise-contrastive estimation (NCE) loss where 8 negative classes are sampled for every batch instead of computing the entire softmax output. All models are trained over a maximum of 300,000 training steps with SGD with learning rate 1 and a batch size of 512. Training is terminated early when the average loss over 2000 training steps does not change considerably for 5 consecutive non-overlapping 2000-step periods. Because training the model is only the surrogate task in order to obtain the embedding, we train on all available data which comprises 206,514 or 363,260 pairs dependent on the window size.

4.3 Frequent Pattern Extraction

4.3.1 Clustered n -grams

We refer to finite sub-sequences of clickstreams as frequent patterns if they appear various times across different students, study sessions, and assessment weeks. Our goal is to automatically extract frequent patterns which represent some kind of strategy or high level task students are fulfilling. As an example, the sequence [Login - View post office - View general post] could be interpreted as an attempt to catch up on the course news.

Pattern mining in educational data mining can lead to relatively unstable results. In order to increase robustness, we examine and compare the results of two distinct procedures for frequent pattern extraction. The first method resembles the procedure proposed by [33], and consists of a multi-step procedure which first extracts a large set of candidate patterns, and then narrows the selection down by similarity grouping. Formally, we proceed according to the following steps:

- (1) **All n -grams.** We extract n -grams, i.e. consecutive sub-sequences of n clicks, from the session clickstreams. Since we expect very short patterns to be uninterpretable, and particularly long patterns are rare in our dataset, we choose $n = 3, 4, 5$.
- (2) **Candidate patterns.** Only the most frequent patterns are kept as candidates for further analysis. Following some experimentation, we choose to keep the most frequent 1 % of patterns of each length.
- (3) **Hierarchical clustering.** The set of candidate patterns can be expected to be repetitive in the sense that patterns might be similar but vary in length or differ in a single click action but yield the same interpretation. To address this issue, we automatically group candidate patterns by agglomerative clustering with average linkage. The number of clusters, and thus of final frequent pattern categories, is chosen by visual inspection of the model's dendrogram.

The final step of this procedure requires us to specify a notion of similarity between patterns. In some sense, it is natural to draw on a string distance measure as sequences of clicks resemble many of the characteristics we would expect from natural language. While the authors of [33] draw on the traditional Levenshtein distance, we choose the Jaro-Winkler distance between two patterns p_1, p_2 measured by $1 - jw(p_1, p_2)$, where $jw(\cdot, \cdot)$ denotes the Jaro-Winkler similarity. Jaro-Winkler distance is an adaptation of more traditional edit distances which takes the sequence length as well as common starting sub-sequences into account. This allows more sensible measuring of similarities between repetitive patterns of different lengths such as the 3-gram [View general post - View general post - View general post] and the 5-gram [View general post - View general post - View general post - View general post - View general post]. Intuitively, the two patterns should have a low distance and in fact, their Jaro-Winkler distance is approximately 0.093 while their normalized Levenshtein distance is 0.4. For our

purpose, we treat each click as a character that can be exchanged or transposed for a penalty on the distance. Then, the Jaro similarity is defined as

$$j(p_1, p_2) := \begin{cases} 0 & \text{if } m = 0, \\ \frac{1}{3} \left(\frac{m}{|p_1|} + \frac{m}{|p_2|} + \frac{m-t}{m} \right) & \text{else,} \end{cases}$$

where m is the number of matching clicks within an index window of $\lfloor (\max\{|p_1|, |p_2|\}/2) \rfloor - 1$, and t is half the number of required transpositions for matching clicks. Further, the Jaro-Winkler similarity is defined as

$$jw(p_1, p_2) := j(p_1, p_2) + \frac{l}{10}(1 - j(p_1, p_2)),$$

where l is the length of a common starting sequence between p_1 and p_2 (at most 4). The additional scaling ensures that distances are normalized to lie in $[0, 1]$.

4.3.2 Topic Model

The clustered n -grams procedure of extracting frequent patterns is easy to implement and model-free. However, it requires us to choose several hyperparameters such as the size of n -grams, the share of candidate patterns, or the number of clusters. It is also likely that the exact choice of the edit distance in the clustering step has a non-negligible effect on the observed results. In order to test our results for robustness, we employ a second method for pattern extraction and compare the resulting student strategies. This method draws on the idea that session clickstreams resemble sentences, individual clicks resemble words, and there is some notion of semantic to a sequence of clicks. Based on these similarities, we use Latent Dirichlet Allocation (LDA), a common NLP model that allows automatic extraction of topics from written documents.

LDA is a Bayesian model which, in our case, is build on the assumption that each session clickstream is a mixture of patterns and each pattern is a mixture of clicktypes. We use the words pattern and topic interchangeably here. While the clickstreams (and hence clicktypes) are given to the model, the topics are latent and can be inferred from the fitted model. The prior on the session clickstream generation assumes that M clickstreams of lengths N_1, \dots, N_M are drawn according to the following steps. (1) Draw a topic distribution $\theta_i \sim \text{Dir}_k(\alpha)$ for each $i = 1, \dots, M$, where k is the number of topics. (2) Draw a click type distribution for topics $\phi_i \sim \text{Dir}_V(\beta)$ for each $i = 1, \dots, V$, where V is the number of different click types. (3) For each click position i, j with $i \in \{1, \dots, M\}$ and $j \in \{1, \dots, N_i\}$, first, choose a topic according to $z_{ij} \sim \text{Multinomial}(\theta_i)$, and second, draw a click type from $w_{ij} \sim \text{Multinomial}(\phi_{z_{ij}})$. LDA comes with three hyperparameters: the prior Dirichlet parameters α and β which express some prior belief on how the mixtures of topics and click types are composed, and the number of latent topics k . While we set the prior Dirichlet parameters to suggested default values, i.e. normalized asymmetric priors, the number of latent topics requires some more thought. Recent research suggests the use of topic coherence measures for comparison of models with different choices of k [34, 43]. On a high level, topic coherence attempts to measure semantic similarity between high scoring words (or here click types) in each topic which gives some indication of how interpretable the topics in question are. We experiment with

several numbers of topics ranging around the number of frequent patterns extracted by the clustered n -gram technique. Since no significant differences in coherence can be observed, we resort to using the same number of topics as for the clustered n -gram method for the sake of comparison.

4.4 Prediction Models

Frequent patterns counts as features. In order to explore what role the extracted strategies play in homework solving versus exam preparation and whether they drive success, we build two prediction models based on patterns counts from the clustered n -gram method. For this, a representative pattern of 3 clicks is chosen for each of the devised strategy clusters, and its occurrences in each of the session clickstreams is counted by comparing against each 3-gram derived from the clickstream. Since we cannot expect the chosen pattern to accurately represent the whole cluster, we allow a Jaro-Winkler distance up to 0.2 when comparing the sub-sequences. This procedure allows matching of click sequences with only one replacement ($1 - jw(abc, abd) \approx 0.18$), one transposition ($1 - jw(abc, acb) \approx 0.10$), or one replacement and one transposition ($1 - jw(abc, adb) \approx 0.20$). In order to build student and assessment week based prediction models, we aggregate pattern counts along assessment weeks and individual students by simple addition. Similar methods have been employed by [8, 29, 42, 10].

Predicting assessment type. A random forest classifier is trained to predict the assessment type, i.e. homework or exam, from frequent pattern counts, the number of clicks, and the number of session clickstreams a student has within a given week. In practice, it is unlikely that we would need to predict the assessment type as it is usually known. However when paired with careful analysis of feature importance and partial dependence, such model can yield valuable insights into the most important differences in student behavior between homework and exam weeks. We use 80 % of the 1,148 student-week combinations for training and hold back 20 % as test set. Hyperparameters including the maximum tree depth, the maximum number of features to consider at splits, the minimum number of samples per leaf, and the number of trees are chosen by a grid search over a range of values, where models are trained with 5-fold cross validation on the training set. Our model draws on Gini impurity to measure the quality of splits, and we evaluate feature importance based on the mean decrease in impurity (MDI) associated with splitting at a given feature when predicting Y . For a set of fitted trees $\mathcal{T} = \{T_1, \dots, T_N\}$, the MDI of a feature X_m is defined as

$$\text{MDI}(X_m) = \frac{1}{N} \sum_{T \in \mathcal{T}} \sum_{t \in T: v(s_t) = X_m} p(t) \Delta i(s_t, t), \quad (1)$$

where $p(t)$ is the proportion of samples that reaches node t , $v(s_t)$ is the variable used to split s_t , and $\Delta i(s_t, t)$ is the decrease of impurity generated by the split.

Predicting grade outcomes. Similar to the assessment type prediction model, we train a random forest regressor to predict students' grade outcomes based on strategy counts, the number of clicks, the number of session clickstreams, and attendance information. The additional consideration of lecture and recitation attendance requires us to remove all observations from finals week, since no face-to-face class time

Figure 3: Euclidean distances of click type embeddings based on skip-gram neural network. Darker color suggests that embedding are close. Proximity in the embedding space suggests clicks generally appear in similar contexts. Rows and columns are clustered for visualization.

has taken place in the last week of the course. Since this constitutes half of all exam observations in the data and grade distributions of homeworks and exams are significantly different ($p < 0.001$), we limit our prediction model to homework grade prediction entirely. Of the 820 homework samples, 80 % are used for training and 20 % for testing. A grid search of hyperparameters with 5-fold cross-validation on the training set is performed, and feature importance is measured analogous to Equation 1 with the MSE as impurity measure.

5. RESULTS

5.1 RQ1 How do students interact with course material, and what are frequent strategies they take?

5.1.1 Context Of Click Types

In order to gain some initial understanding of online student behavior, we explore the contexts in which different types of actions are performed by deriving a skip-gram neural network based embedding of actions. After exploring a small grid of hyperparameter values, our skip-gram is trained on data pairs with window size 1 to learn a 4-dimensional embedding. Figure 3 depicts the Euclidean distances between the embedding vectors of different click types based on the model. Proximity of embeddings suggests that click types either appear in a similar context, i.e. within a few clicks of each other, or are interchangeable actions, i.e. have the same context. In other words, by exploring which actions lie close to a given click type in the embedding space, we can gain some insight into the set of clicks students typically

make right before and after. It is noteworthy that some types of actions appear together by design of the Diderot system, e.g. in order to comment on a post, the post has to be loaded. Figure 3 reflects many of these expected relations which gives some validation to our methodological approach.

Our results suggest several broad clusters of student actions. The block in the upper left corner of Figure 3 appears to focus on active discussion participation including click types such as **Like post** or **Create comment**. The next block is somewhat close to many of the active discussion actions and concentrates on scrolling through the discussion board represented by **View post office** type actions. Although more rigorous statistical analysis is needed, the results suggest some interesting interpretations:

- (1) **Students ask more questions about homeworks than about any other course materials.** This interpretation is based on the proximity of **Create post** to **View homework atom** which appears to be much closer than any other **View atom** type action. This suggests that student questions, comments and clarifications are more common for homework material than for lectures notes, recitation material, practice exams, or the library documentation.
- (2) **Students are more likely to interact with course-wide posts than material specific discussions.** The action **View general post** is close to interactive behavior such as **Create comment**, **Like post** or **Follow post** while **View atom post** appears to be performed mostly in a different context. This suggests that discussion-specific reactions and interactions concentrate mostly on general posts such as course announcements or social posts and are less common for questions and comments concerning particular parts of the course materials.

Overall, context analysis for click types based on skip-gram neural networks provides us with some valuable understanding of students' use of Diderot. The same method might be useful to other practitioners, in particular, for initial exploration of data collected through educational software systems. It appears that interpretable low-dimensional embeddings of a medium number of action types can be obtained with only a few weeks worth of data from a single college course which renders this method particularly useful for blended courses.

5.1.2 Frequent Pattern Extraction

Patterns are extracted with two distinct methods, and subsequently interpreted in terms of underlying student strategies. A summary of the results and comparison between the methods is given in Table 2. The left side of the table shows the results of the clustered n -gram pipeline for pattern extraction. The most frequent 1% n -grams for each $n = 3, 4, 5$ are extracted from the session clickstreams. This yields a candidate set of 223 sequential patterns which are clustered into 9 groups based on agglomerative clustering with average linkage and Jaro-Winkler distance as distance function. The number of clusters is informed by visual inspection of

Table 2: Comparison of student strategies extracted by clustered n -gram method and LDA. Patterns in the first block (B1) consist of exactly the same click types, while other patterns show differences but allow for similar interpretations (B2). Lastly, the LDA method finds a mixture of practice exam related patterns and a new load course pattern (B3).

	Clustered n -gram method		LDA method	
	Student strategy	Associated click types	Student strategy	High weight click types
B1	Look at lecture notes	View lecture notes chapter (75.88 %)	Look at lecture notes	View lecture notes chapter (1)
	Look at homeworks	View homework chapter (100 %)	Look at homeworks	View homework chapter (0.826)
	Look at recitation material	View recitation chapter (100 %)	Look at recitation material	View recitation chapter (0.712)
B2	Catch up on news	View general post (52.04 %), View main post office (24.3 %), View atom post (16.13 %)	Catch up on news	View general post (0.543), View main post office (0.410)
	Active homework engagement	View atom post (50 %), View homework atom (31.02 %), View general post (10.65 %)	Active homework engagement	View atom post (0.653), View homework atom (0.344)
	In-depth review of lecture notes	View lecture notes atom (50 %), View atom post (28.57 %), View lecture notes chapter (21.43 %)	In-depth review of lecture notes	View lecture notes atom (0.483), View atom post (0.31), Click link lecture notes (0.195)
	Look at library documentation	View library documentation chapter (85.29 %)	Look at library documentation	View library documentation chapter (0.674), Search atom (0.321)

	Look at practice exams	View practice exams chapter (100 %)	Load course	Load course (0.998)

the respective dendrogram. It is noteworthy that the clusters appear to have imbalanced sizes with the largest cluster including 106 candidate patterns, and the smallest clusters containing only 2 or 3 of the candidate patterns. Yet, inspection of the associated click types and their in-cluster frequencies allows for intuitive interpretations as student strategies. Multiple of the devised strategies revolve around passive review of materials such as lecture notes, homeworks, recitation material, library documentation (which includes code snippets for reference), or practice exams. More involved strategies are given by active homework engagement, in-depth review of lecture notes, catching up on course news, and going through practice exams. For example, the catching up on course news strategy is associated with sequential patterns involving reading of general posts, atom posts, and loading the main post office page.

The right side of Table 2 summarizes the results of pattern extraction based on Latent Dirichlet Allocation (LDA). For the sake of comparison, we keep the number of extracted patterns fixed and derive 9 student strategies. By assumption of the model, each pattern is a mixture of all click types. In turn, extraction of weights is straightforward and we report the click types with highest weights for each pattern. We find that multiple of the extracted patterns match exactly the patterns retrieved with the clustered n -gram method in the sense that they are based on exactly the same click types (B1). Another set of patterns shows small changes in included click types, but essentially provides the same interpretation as the patterns found with the first method (B2). Lastly, the LDA method finds a practice exam strategy which broadly presents a mixture of the two practice exam related strategies from the first model, and a load course strategy which almost entirely consists of the **Load course** action (B3). The load course pattern likely arises from the session clickstreams with a single click

which present 30.30% of the session clickstreams. A total of 56.66% of these one-click sequences are **Load course** actions. Reasons for these single **Load course** clicks can be manifold. In some cases, students might get distracted immediately after loading the course, or they have to reload the course multiple times. However, we hypothesize that in most cases, the course overview page which is loaded when loading the course provided all information the student was looking for since it includes recent updates, posts and announcements. Contrary to the clustered n -gram method which only takes into consideration session clickstreams of at least three clicks, LDA can leverage even these short clickstreams. Yet, the additional insights gained through the load course pattern are marginal since it very short and hard to interpret as a strategy.

All in all, both methods roughly extract the same strategies which speaks in favor of the validity of both approaches. One could argue that the clustered n -gram method yields slightly more tangible insights since the patterns present actually frequently occurring sub-sequences. However for larger data sets, the method can become computational expensive rendering LDA a better choice.

5.2 RQ2 How do students use these strategies for homework solving as compared to exam preparation?

We extract strategy features for assessment week level prediction models by matching session clickstreams against the extracted frequent patterns. The results are summed up for each student-week combination and thus roughly represent how often a given student has used a strategy in a given assessment week. After this aggregation, 91.03 % show at least one occurrence of one of the patterns. We generally expect not all student click behavior to follow the extracted strate-

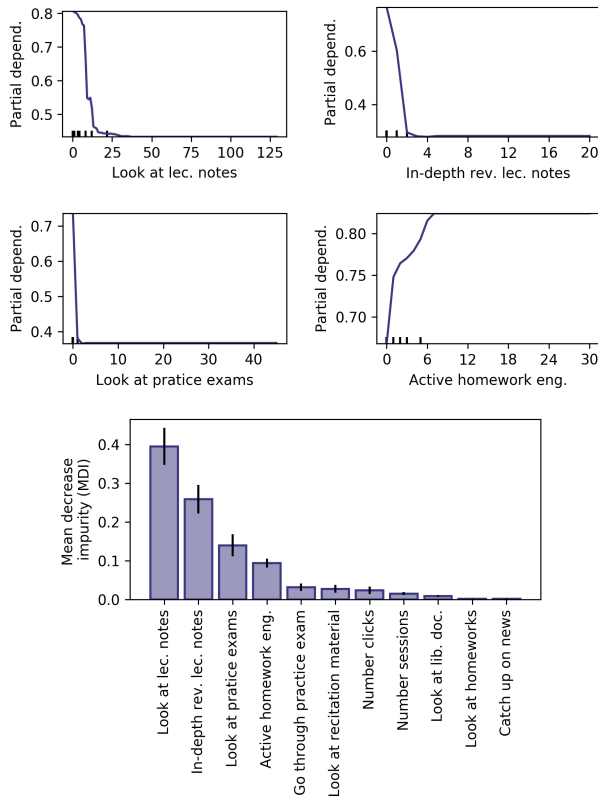

Figure 4: Relative feature importance for assessment week random forest prediction (1 = homework, 0 = exam) along with 95 % confidence intervals (bottom) and partial dependence plots for the most important features (top). Features include strategy counts from the clustered n -gram method, the number of clicks and the number of session clickstreams.

gies or stringent strategies at all. Thus, it is unsurprising that some of the student week combinations do not involve any of the patterns.

We train a random forest classifier to predict the assessment type on pattern counts, the number of clicks and the number of sessions within a given week. A total of 80 % of the data is used for hyperparameter tuning and training, while 20 % is withheld for testing. The model reaches a classification accuracy of 93.68 % on the training data which constitutes an evident improvement over the naive majority class prediction (71.90 % of the training data have the label homework). Based on a permutation test, we find that the model performs better than random on the training set ($p < 0.01$). A total of 100 permutations of labels were used for this evaluation. Accuracy on the test set is 93.91 % which suggests sufficient generalization ability of the prediction model.

The prediction model results suggest that students use the educational support system differently and employ the different strategies at different rates when preparing for exams as compared to doing homeworks. We examine feature importance in the model in order to gain more insights into these differences. Figure 4 depicts the mean decrease in impurity (MDI) for splits at the different covariates, as well as partial dependence of the predictions on the most impor-

tant features. We see that predictions are mainly driven by pattern counts of the strategies look at lecture notes (MDI = 0.395), in-depth review of lecture notes (MDI = 0.259), look at practice exams (MDI = 0.140), and active homework engagement (MDI = 0.094). Partial dependence plots show that while increased counts in the strategies related to lecture notes and practice exam engagement increase the probability that the model predicts an exam week, higher counts in the active homework engagement strategy increase the models likelihood of predicting an upcoming homework deadline. These results suggest that students approach to learning is driven by the kind of performance assessment they are given. It appears that the increased activity in exam weeks (see Figure 1) is largely based on increased engagement with lecture notes and practice exams, while interactions with the homework related content is generally less pronounced.

5.3 RQ3 Are student strategies indicative of grade outcomes?

We train a random forest regression model to predict homework grades on a individual week and student level. Features include students’ strategy counts, the number of clicks, the number of sessions, and the mean attendance in both lectures and recitations. Training is conducted on 80 % of available data while 20 % are withheld for testing. After hyperparameter tuning with 5-fold cross validation, the prediction model realizes a MSE of 0.046 on the training data set. A permutation test based on 100 permutations of labels shows a significant improvement over random performance with this model ($p < 0.01$). On the test set, the model attains a prediction MSE of 0.054 which suggests sufficient generalization ability.

Figure 5 explores the importance of the different features for predictions and displays partial dependence relations for the most important covariates. Since we use MSE as impurity measure, the mean decrease in impurity (MDI) for a given feature effectively corresponds to the mean decrease in variance we receive by splitting at the feature. We see that, in fact, the most relevant features appear to be the number of clickstream sessions (MDI = 0.311), the number of clicks (MDI = 0.221), lecture attendance (MDI = 0.123), and recitation attendance (MDI = 0.112). Partial dependence plots reveal that increases in any of the above features increase the predicted homework score percentage by a relatively large margin of up to 20 percentage points. Conversely, strategy counts appear to be less relevant for grade predictions with some exceptions. Most notably, the predicted grade rises with the number of times students actively engaged in homeworks (MDI = 0.077).

Overall, our results show some success in prediction of homework grade outcomes. The extracted features, including some of the pattern counts, add valuable information to the prediction model. In particular, students who come back to Diderot more often and thus use an increased number of study sessions to solve their homeworks, and students who generally interact with the system at high rates are predicted to have better grade outcomes. In addition to time at task, the mere attendance in lectures and recitations increases students’ grade outcome predictions. In fact, students in the our data set who attended at least one lecture in a given

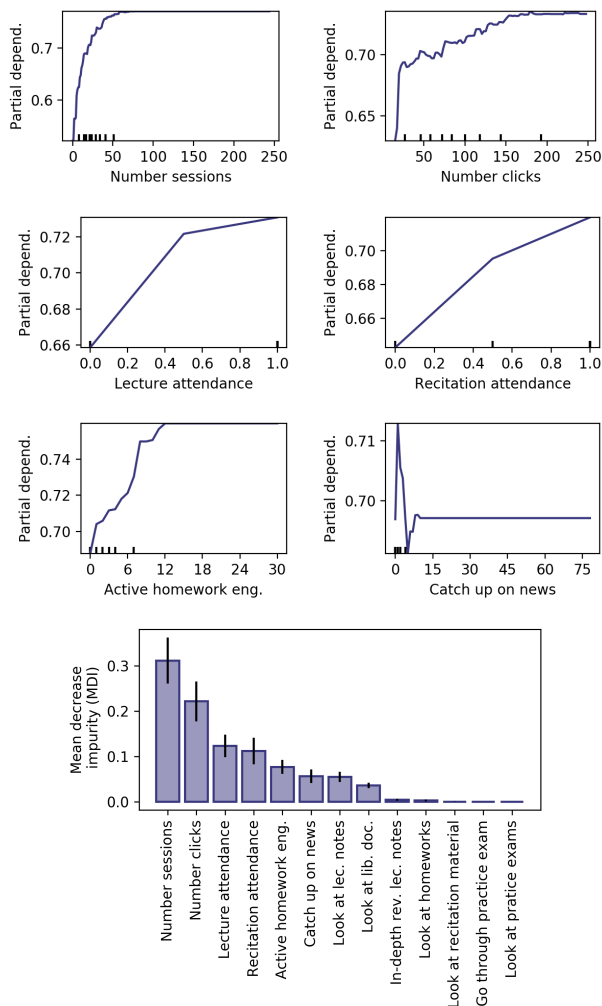

Figure 5: Relative feature importance for homework grade random forest prediction along with 95 % confidence intervals (bottom) and partial dependence plots for the most important features (top). Features include strategy counts from the clustered n -gram method, the number of clicks and session clickstreams, and attendance information.

assessment week on average received a homework percentage grade of 76.58 %, while students who skipped lectures on average scored 55.86 %. For recitation attendance this corresponds to 74.34 % and 49.20 % respectively.

Both of the discussed prediction models provide valuable insights for instructors and educational system design. The tree-based ensemble methods are particularly suitable for initial modeling and processing of features on different scales. Their main advantage over many other models is the relatively straightforward explainability of predictions given partial dependence plots and measures of feature importance which renders them a useful approach to high stakes at-risk prediction.

6. CONCLUSIONS

Data from educational software systems provides insights into students’ study behaviors. While performance predic-

tion in MOOCs has been explored extensively, similar studies for blended courses are scarce and often lack a deeper understanding of the underlying student strategies. Based on fine-grained contextualizable click data collected through the non-commercial course support system Diderot, we explore how students interact with educational software systems, which strategies they employ to engage with course materials and in which ways strategies depend on the assessment type and drive performance. Our contributions are two-fold: (1) We gain relevant understanding of students’ learning behavior that both confirms and adds to the existing literature. (2) We propose new NLP-inspired approaches to analyzing student strategies’ based on clickstream data in blended learning scenarios which typically come with moderately sized data sets.

On the educational side, our results provide valuable insights into how students interact with course systems. In line with previous research [38, 1], we observe increased activity before deadlines, and, in particular, in the days leading up to an exam. Exam preparation appears to come with increased review of lecture notes as compared to homework solving. In general, students seem to ask more questions related to homeworks as compared to other class materials such as lecture notes, recitation materials or practice exams. At the same time, interactions with already existing posts such as liking or commenting seems to concentrate mostly on course-wide announcements, social posts and course feedback discussions and appears to be less common for direct questions on course materials. Many of the derived features have some predictive power for performance outcomes. In particular, the number of study sessions, the number of clicks, attendance in lecture and recitation, and engaging with homework related course content are strong predictors for homework grades in our model. The described observations are entirely based on data from a seven week period of a large sophomore level college course since technical difficulties prohibited collection of data for the remainder of the semester. In the future, more complete data (e.g. from an entire course, or even multiple courses such as the same course offering over several years) could provide an enhanced understanding of student behavior and allow the tackling of more complex problems such as the simultaneous prediction of homework and exam grades which, such as in our data, can have very different distributions.

The methods proposed in this work promise to be useful to a broad range of researchers and practitioners who find themselves analyzing activity log-data from blended courses, or are at the initial stages of developing early warning systems. The key insight of this work is that hybrid NLP methods can be used to thoroughly analyze contexts of actions as well as frequent strategies in the relatively low-data setting of blended courses. To the best of our knowledge, similar models have previously only been employed in the setting of MOOCs [e.g. 44, 37]. In fact, our analysis shows that topic models such as latent Dirichlet allocation can recover almost the same student strategies as more traditional data mining based pipelines of pattern extraction, and small versions of skip-gram neural networks can provide valuable insights into the context of student actions even with moderately sized data sets.

ABSTRACT

With the increased number of MOOC offerings, it is unclear how these courses are related. Previous work has focused on capturing the prerequisite relationships between courses, lectures, and concepts. However, it is also essential to model the content structure of MOOC courses. Constructing a precedence graph that models the similarities and variations of learning paths followed by similar MOOCs would help both students and instructors. Students can personalize their learning by choosing the desired learning path and lectures across several courses guided by the precedence graph. Similarly, by examining the precedence graph, instructors can 1) identify knowledge gaps in their MOOC offerings, and 2) find alternative course plans. In this paper, we propose an unsupervised approach to build the precedence graph of similar MOOCs, where nodes are clusters of lectures with similar content, and edges depict alternative precedence relationships. Our approach to cluster similar lectures based on PCK-Means clustering algorithm that incorporates pairwise constraints: Must-Link and Cannot-Link with the standard K-Means algorithm. To build the precedence graph, we link the clusters according to the precedence relations mined from current MOOCs. Experiments over real-world MOOC data show that PCK-Means with our proposed pairwise constraints outperform the K-Means algorithm in both Adjusted Mutual Information (AMI) and Fowlkes-Mallows scores (FMI).

Keywords

Precedence Graph, Clustering, Pairwise Constraints, Precedence Relations, Alternative Learning Paths, Common Learning Path.

1. INTRODUCTION

According to Class Central [19], by the end of 2019, over 13 thousand MOOCs have been announced or launched by more than 900 universities worldwide. With such an increase in online courses, it becomes increasingly hard for learners to understand similarities and differences among courses that cover similar topics. For instance, Coursera¹, one of the leading MOOC platforms, offers

Fareedah Alsaad and Abdussalam Alawini "Unsupervised Approach for Modeling Content Structures of MOOCs" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 18 - 28

several "Machine Learning" courses, such as "Machine Learning" from Stanford University, "Machine Learning with Python" offered by IBM, "Machine Learning for All" from University of London, etc. Understanding the content structure across such similar courses can be very challenging. Consequently, MOOCs users may waste time choosing a course among a broad set of similar MOOC offerings.

Previous work studied ways for capturing prerequisite relationships between courses [23, 11], between lectures within (or among) courses [5, 6], or between concepts discussed within (or across) courses [2, 10, 15, 23, 11]. While modeling prerequisite relationships is crucial for understanding the content and knowledge structure of a specific domain, prerequisites do not reveal content overlap in similar courses. Further, modeling MOOC content in terms of prerequisite relations cannot detect the variations in the learning path between similar MOOCs.

In this paper, we propose to model the content structure of similar MOOC offerings as a precedence graph. This graph can be useful for both learners and instructors. Learners can use the graph to build a customized learning plan as well as to explore how various courses explain the same topic. As for instructors, the graph can be used to identify any missing knowledge in their MOOCs offering, hence help them improve their courses. Section 3.2 elaborates on other possible applications of our proposed MOOCs precedence graph.

More precisely, we introduce an unsupervised approach to model the content structures of MOOCs. Figure 1 demonstrates the proposed idea. Given a set of courses that have some overlap in their content, we first cluster lectures based on their content similarity into clusters; each cluster represents a node in the precedence graph (see Figure 1 (b)). Then, the clusters are linked according to their lectures precedence relations mined from current MOOCs as depicted in Figure 1 (c). Linking clusters of similar content based on the precedence relations can reveal the various possible paths followed by similar courses and also capture which path is considered more common in these courses.

To cluster lectures based on their content similarity, we utilize a constraint-based clustering algorithm called Pairwise Constrained K-Means (PCK-Means). PCK-Means guides the clustering process by using two constraints: Must-Link and Cannot-Link. The idea is to guide the clustering process, by using the constraints, to focus on clustering lectures across courses instead of within courses to capture the similarity between courses. To measure the content similarity between lectures, we exploit both lecture titles and transcripts as they both encode enough information about the content of lectures. By using cosine similarity, we measure the similarity between lectures

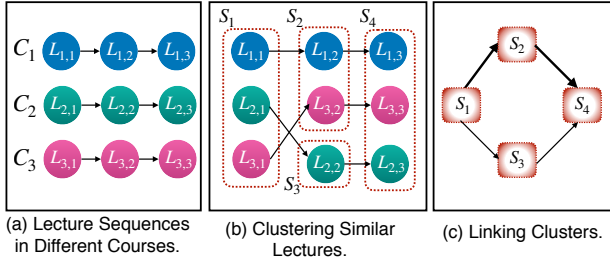

Figure 1: The basic idea of modeling the content of MOOCs to construct the precedence graph. Given similar Courses with some overlaps in content represented as sequences of lectures, the precedence graph is constructed by clustering lectures based on content similarity and link the clusters using the precedence relations between lectures.

and construct the constraint examples to guide the clustering process. Our experiment on real MOOC dataset shows that PCK-Means with our proposed constraints outperforms standard K-Means algorithm in both Adjusted Mutual Information (AMI) and Fowlkes-Mallows scores (FMI).

After clustering similar lectures, we construct the precedence graph by linking clusters based on the precedence relations and label clusters using salient and key terms in each cluster. The generated precedence graph reveals the popular learning path and some alternative paths in our MOOCs dataset.

The rest of the paper is organized as follows. Section 2 presents related work. In section 3, we demonstrate the idea of modeling the content structure of MOOCs by an illustrative example and also present some applications of the precedence graph before we formally define our problem in Section 4. Section 5 describes how we represent the content of MOOCs using word count and embedding representations. In section 6, we explain PCK-Means algorithm and present our method of generating the lists of pairwise constraints. In section 7, we demonstrate the process of linking and labeling clusters to construct the precedence graph. Section 8 elaborates on our approach for the evaluation and presents some learning path examples extracted from the generated precedence graph. Finally, we conclude our work in section 9.

2. RELATED WORK

There has been recently a growing body of work that addresses the problem of modeling the content of MOOCs. Most of this work has focused on capturing the prerequisite relationships between courses [23, 11], between lectures or segments of lectures [5, 6], or between concepts discussed within or across courses [2, 10, 15, 23, 11]. These studies have developed supervised and unsupervised approaches to model only the prerequisite relations in MOOCs. In this paper, we go further and develop an unsupervised approach to capture the similarities and variations of learning paths between MOOCs in the same domain. Our work models the precedence relations (i.e., the implicit prerequisite relationships) between concepts by clustering similar lectures among different courses. Therefore, our model can reveal popular learning paths shared by several courses along with alternative possible paths to learn the topic covered by these similar courses.

To model the prerequisite relationships, some studies have used external knowledge such as Wikipedia to support identifying educational concepts [10] or to represent concepts using Wikipedia articles or categories [15, 23, 11]. Using Wikipedia to identify concepts has some weaknesses: (1) some concepts are not included in Wikipedia [15] and thus can affect the performance of the model, (2) the mapping between course concepts to Wikipedia is not always accurate, which can affect the quality of the extracted concepts [10], and (3) using Wikipedia categories affects concept granularity by preferring more general concepts [2]. Instead of using Wikipedia, the work by ALSaad et al. [2] has exploited pre-trained part-of-speech-guided phrasal segmentation to extract phrases from course content and then manually group synonym phrases to represent concepts. In our work, instead of relying on external knowledge or manually improve the concepts, we represent the precedence graph nodes by salient terms using simple TF-IDF and bag-of-words representations. Our method represent each cluster with key terms by accumulating lecture representation vectors of each cluster and exploiting the top ranked words to represent clusters. Accumulating the vector representations of similar lectures helps in extracting representative terms that express the content of each cluster clearly.

Another related line of work is the use of prerequisite relations between concepts to organize learning units and predict the precedence relationships between them [1, 13]. The studies [1, 13] have proposed supervised approaches that rely on features extracted from external knowledge such as Wikipedia [1] and DBpedia [13] to infer the prerequisite relations between concepts. While the work [1] assumed that concepts are given, the study [13] manually extracted concepts by annotators. Our work is different as instead of inferring the prerequisite relations between concepts and then organizing them according to the precedence relations, we leverage the precedence relations between lectures in existing MOOCs to detect the precedence relations between the nodes in the precedence graph. Each node in the precedence graph is labeled automatically with key concepts that clearly express the content of each node without the use of external knowledge.

The work by Shah et al. [20] is the most relevant work to ours. The study has proposed a method for linking similar courses to construct a map of lectures connected by two types of relations: similar and prerequisite. The goal of the map is to help students find the desired learning path that fits their interests and backgrounds. Our work is very similar as we construct the precedence graph that depicts the different possible learning paths. However, instead of linking lectures by similar and prerequisite relations, we cluster lectures based on content similarity and connect clusters according to the precedence relations. Our approach reveals the similarities and variations of learning paths between different courses by capturing popular learning paths shared by many courses in the domain, hence emphasizes the importance of the common, comprehensive and alternative learning paths.

3. MODELING MOOCs CONTENT

In this section, we explain the idea of modeling the content of MOOCs as a precedence graph by using an illustrative example. We also discuss possible applications of the mined precedence graph.

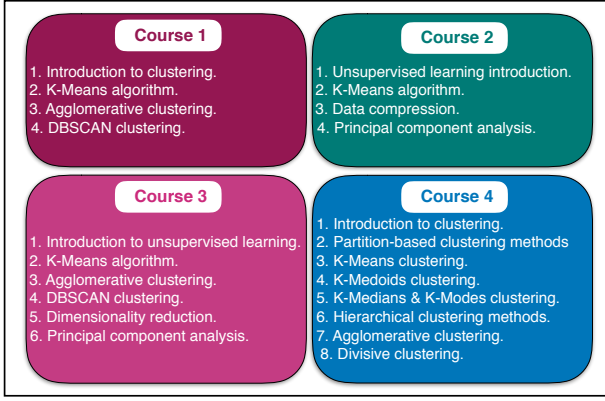

Figure 2: The sequence of lectures in four different courses that explain the topic Unsupervised Learning.

3.1 An Illustrative Example

For illustration purposes, let us assume that a MOOC platform offers four courses about *Unsupervised Learning* topic in machine learning as shown in Figure 2. Each course explains the topic using a sequence of lectures. As can be seen in Figure 2, there are some overlaps between these four courses as they all teach the same topic, but there are also some variations. The variation in each course is based on instructors' perspectives and background about the topic, instructors' teaching styles, and also the learning objective of each course. Some courses are abstract as they focus on the theory behind the topic while other courses are more concrete as they demonstrate the topic by illustrating real-world examples. Courses also vary in the coverage of topics as some courses are concise while other courses cover topics in more details. For example, **Course 1** and **Course 2** in Figure 2 are examples of concise courses that focus only on teaching the main concepts in the topic. In contrast, **Course 3** and **Course 4** are examples of courses that elaborate more in the topic by providing more detailed concepts.

Given the similarities and variations between these courses that explain the same subject, we investigate the following questions. *how these courses are related? What are the common concepts taught by the majority of these courses? Is there a common learning path shared by most of these courses? what are the alternative paths to study the topic?* Modeling the content structure of these courses as a precedence graph is a crucial step to help learners and educators with answering these questions.

The first step in building the precedence graph is to cluster lectures based on their content similarity and then construct a node in the graph for each cluster. Figure 3 shows the cluster assignment of each course lecture of Figure 2. As illustrated in Figure 3, all the introductory lectures, the first lecture of each course, are grouped into one cluster (cluster S_1) as all these lectures introduce the topic of *Unsupervised Learning*. Similarly, all the lectures about the concepts “*K-Means Algorithm*”, “*Agglomerative Clustering*”, and “*DBSCAN*” are clustered into three different clusters: S_6 , S_3 , and S_7 respectively. Furthermore, lectures about “*Data Compression*” are clustered into cluster S_{11} while lectures taught “*Principal Component Analysis*” concept are clustered into cluster S_{10} .

After clustering similar lectures and finding the nodes of the precedence graph, the next step in building the graph is to link these

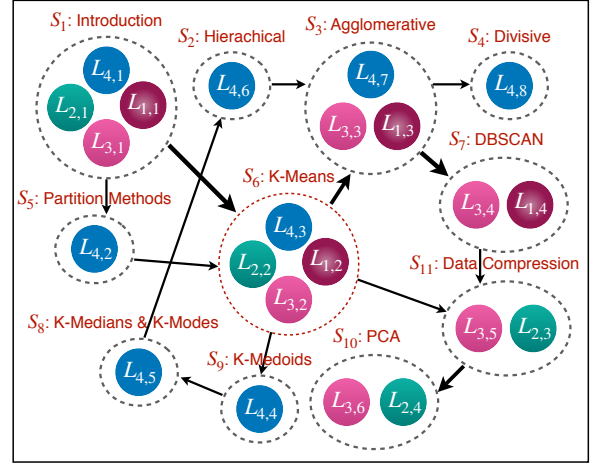

Figure 3: The mined precedence Graph from courses in Figure 2. Lectures are grouped into clusters to construct the nodes of the graph. Edges depict the precedence relationships between clusters where thick edges represent the edges with high weights and thus indicate how common are the relations between the nodes.

scattered clusters to reveal the precedence relations between clusters. To that end, we use the precedence relations between adjacent lectures of the same course to construct the edges between nodes (clusters) in the precedence graph. For instance, we add a directed edge from cluster S_5 to cluster S_6 to determine the precedence relation between these two nodes according to the sequence of lectures 2 and 3 in course 4. To reflect the strength of each precedence relations between two nodes (i.e., how common are the relations between the nodes), we attach each edge in the precedence graph with different weights. Edge weights are calculated by accumulating the frequency of lecture sequences in various courses. For example, as shown in Figure 3, the strength weight of edge $S_1 \rightarrow S_6$ should be higher than the strength weight of edge $S_1 \rightarrow S_5$ as three out of the four courses (1,2, and 3) have the sequence $S_1 \rightarrow S_6$ while only one course (4) shows the sequence $S_1 \rightarrow S_5$.

As mentioned earlier, the mined precedence graph can help us in revealing some hidden structures in similar MOOCs. For instance, it is clear from Figure 3 that the path $\{S_1 \rightarrow S_6 \rightarrow S_3 \rightarrow S_7\}$ is more common than other paths. The reason is that three courses (1,2, and 3) explain the concepts “*K-Means Algorithm*” after introducing the topic and two of them (courses 1 and 3) present the concepts “*Agglomerative Clustering*” and “*DBSCAN*” after that. In addition to indicating the common path, the mined precedence graph can also reveal other possible paths to learn the topic such as the path $\{S_1 \rightarrow S_5 \rightarrow S_6 \rightarrow S_3 \rightarrow S_4\}$, or the path $\{S_1 \rightarrow S_5 \rightarrow S_6 \rightarrow S_{11} \rightarrow S_{10}\}$. All these paths are valid and, off course, choosing a path depends on students' learning objectives.

In general, the mined precedence graph helps in capturing the similarities and variations of the learning paths of similar courses in our illustrative examples. In section 8.3, we present some learning path examples from the precedence graph generated by our approach.

3.2 Precedence Graph Applications

Our mined precedence graph can be used to support several applications for improving the learning and teaching process. However,

before discussing these applications, we first want to clarify that (in this paper), we define a student as a person who uses MOOCs as modularized resources to learn topics of their choice (as opposed to taking a full course as part of a certificate program.) According to Zheng et al. [24], one of the motivations for a student to register for a MOOC is to learn some desired concepts on-demand. Once they achieve their learning goals, this type of student usually stops participating in the course.

Our precedence graph can support the following applications.

Personalized (customized) course plans. Our precedence graph can help students develop custom learning plans. Students can examine the graph to identify possible alternative paths for learning a topic and then choose the path that best fits their needs. For instance, a student might choose to follow one of the following two paths: $\{S_6 \rightarrow S_9 \rightarrow S_8\}$ or $\{S_6 \rightarrow S_{11} \rightarrow S_{10}\}$ shown in Figure 3. The former path helps the student explore and learn about various clustering algorithms: “K-Means Algorithm”, “K-Medoids Algorithm”, and “K-Medians and K-Modes Algorithms”, while the latter path helps the student learn about the concepts of “Data Compression”, and “PCA” with “K-Means” clustering algorithm.

An overview/summary of a topic. There are two ways in which the precedence graph can be used to help students obtain a quick overview of a particular topic of interest. First, students can use the graph to follow the most common path that is shared among several courses (i.e., the path with the highest edge weights.) For instance, students can follow the path: $\{S_1 \rightarrow S_6 \rightarrow S_3 \rightarrow S_7\}$ as this is the path with the highest edge weights in the graph shown in Figure 3. This path introduces the topic of *Unsupervised Learning* first before presenting three important and well-known clustering algorithms: “K-Means Algorithm”, “Agglomerative Clustering Algorithm”, and “DBSCAN Algorithm”. Second, using summarization algorithms, we can generate a summary of the lectures in each node (cluster) of the most common path in the precedence graph. Such a succinct representation of clusters would provide students with a concise summary of the topic they want to learn.

Acquiring expert knowledge. Our precedence graph can also be used by students who are interested in becoming experts in a particular domain. The graph allows students to easily determine how the knowledge of a domain is structured. It also allows them to choose the path that exposes them to a variety of concepts related to the topic they want to learn. For example, to learn the most about unsupervised learning, a student can follow the longest path in the precedence graph shown in Figure 3: $\{S_1 \rightarrow S_5 \rightarrow S_6 \rightarrow S_9 \rightarrow S_8 \rightarrow S_2 \rightarrow S_3 \rightarrow S_4 \rightarrow S_7 \rightarrow S_{11} \rightarrow S_{10}\}$. Clustering similar lectures from various courses into the same clusters can also help this type of students as they can explore how different courses explain the same concept.

Helping instructors improve their courses. In addition to helping students with their learning process, the mined precedence graph can also aid instructors in understanding the structure of their MOOC offerings. By examining the precedence graph, instructors can identify potential knowledge gaps (missing topics) or a better ordering of the topics, and hence incorporate the new knowledge in their next course offerings.

4. PROBLEM DEFINITION

The design of a MOOC mimics that of a typical on-campus course in which the fundamental structure is a sequence of lectures. By

leveraging the sequences of lectures and the content similarities between lectures from similar courses, we can model the knowledge structure of similar (i.e., courses that cover the same topic) MOOCs as a precedence graph. The nodes of this graph are groups of similar lectures, labeled by dominant and salient terms in these lectures. The edges of the graph represent the alternative precedence relations between nodes. Each edge can be assigned different weights that reflect the strength of the relation.

We formally define the problem as follows. Given a set of courses $X = \{C_1, C_2, C_3, \dots, C_n\}$, where n is the total number of courses. We assume that all courses in X have the same difficulty level, and there are some content overlaps between courses. Each course C_i is an ordered list of lectures $C_i = [L_{i1}, L_{i2}, \dots, L_{i|C_i|}]$, where $|C_i|$ is the total number of lectures in the course C_i . Each lecture L_{ij} is represented using the title t_{ij} and the lecture transcript d_{ij} . The goal is to model the content structure of similar MOOCs by constructing the precedence graph as a directed graph $G = (V, E)$ where V is the set of nodes, $V = \{S_1, S_2, S_3, \dots, S_{|V|}\}$ (the number of nodes $|V|$ is given), and $E = \{e_1, e_2, e_3, \dots, e_{|E|}\}$ is the set of edges between nodes. Edges in the graph G are directed edges to indicate the precedence relations between nodes. Each node in the precedence graph is a cluster or a group of lectures that have similar content. For example, $S_v = \{L_{i1}, L_{i2}, L_{j5}\}$ is a cluster that has the first two lectures from course C_i and the fifth lecture from course C_j . We represent the precedence graph G as an edge weight matrix $\mathbf{G} \in \mathbb{R}^{|V| \times |V|}$ where each entry of matrix \mathbf{G} contains the edge weight. For instance, the edge weight of the entry g_{ij} reflects the strength of the precedence relationship from cluster S_i to cluster S_j .

To construct the precedence graph, we need first to find the set of nodes V of the precedence graph by grouping similar lectures using both lecture titles t_{ij} and lecture transcripts d_{ij} . Then, we compute the edge weight between pairs of nodes by leveraging the sequence of lecture in each course C_i . Sections 6 and 7 explain our proposed approach to build the precedence graph.

5. MOOC CONTENT REPRESENTATION

In this section, we demonstrate how we represent MOOC lectures by exploiting two representations: 1) *sparse representation* that is based on word count, and 2) *dense representation* to capture the semantic similarity between text. The purpose of using these two representations is to compare how each of them affects the performance of clustering.

To represent lectures, we use the sparse representation, a robust and straightforward representation based on the count of words. We represent lecture titles as vectors of word count using Bag-Of-Words (BOW) representation. Since lecture titles are short and concise, the frequency of each word in the BOW vector is usually one. The bag-of-words representation can be thought of as a bit vector where a bit is set to 1 when the word occurs in the title and set to 0, otherwise.

For representing lecture transcripts, we use the Term-Frequency Inverse-Document-Frequency (TF-IDF) representation. TF-IDF weighting takes into consideration the count of words in documents as well as the popularity of words in the corpus, hence gives higher weights to the words that are more frequent in the document and less popular in the corpus.

In our model, each lecture is represented by two vectors: a BOW vector to represent the title and a TF-IDF vector to capture the content of the transcript. The drawbacks of this representation are 1)

it generates high dimensional sparse vectors, and 2) it cannot capture the semantic similarity between similar words.

To overcome the limitations of TF-IDF and BOW representations, we use an alternative (dense) representation to model MOOC content: the unsupervised smoothed inverse frequency (uSIF) [8]. The uSIF is a simple, yet effective method for generating sentence embeddings without any labeled data. It is an improvement of smoothed inverse frequency (SIF) [18], one of the state-of-the-art embedding representation for longer pieces of text. The basic idea of uSIF is to exploit the pretrained word embeddings such as Word2Vec [14] or Glove [16] that capture the semantic meaning between words to learn the embeddings of sentences and paragraphs taking into consideration the frequency of words in the text. For more information about uSIF, please refer to [8].

For the embedding representation of lectures, we use uSIF with Glove pretrained word embeddings [4] to represent both lecture titles and transcripts. The number of feature dimensions in embedding vectors is 100 dimensions.

6. CLUSTERING LECTURES OF MOOCS

To construct the nodes of the precedence graph, lectures are grouped into clusters based on their content similarity. We can use any clustering algorithm such as K-Means to do the clustering of lectures. However, one problem of using K-Means or some other clustering algorithms is that they will cluster similar lectures not just across courses but also within courses. For example, if one course explains the topic “Gradient Descent in Logistic Regression” and then later explains the topic “Gradient Descent in Neural Networks”, then there is a high chance that the clustering algorithm would group these two lectures into the same cluster as the course instructor would use almost the same terminology to explain these two topics. However, our goal is to capture the similarity of lectures across courses to reveal common learning paths utilized by many courses as well as other alternative learning paths. Therefore, we need to restrict the clustering process to cluster lectures from different courses rather than within the same course. To do that, we need to guide the clustering algorithm by imposing some constraints; which is infeasible with the standard K-Means algorithm. Therefore, we decided to exploit a constraint-based clustering algorithm called Pairwise Constrained K-Means (PCK-Means) [3] to guide the clustering process.

6.1 PCK-Means Clustering Algorithm

PCK-Means clustering algorithm [3] is a variation of the standard K-Means algorithm that incorporates distance between points as well as pairwise constraints to guide the clustering process. PCK-Means is a semi-supervised approach where users provide some labels or pairwise constraints that the algorithm uses to improve the clustering. Since collecting labels from users is expensive, we propose an unsupervised method by automatically find suitable labels or constraints to guide the clustering process (discussed in section 6.2).

Pairwise constraints can be used to determine the prior knowledge about the domain by specifying which instances (in our case lectures) should or should not be clustered together [21, 3]. There are two types of pairwise constraints: **Must-Link** and **Cannot-Link**. Must-Link constraint specifies pairs of instances (lectures) that need to be grouped into the same cluster, while Cannot-Link constraint determines pairs that should not be in the same cluster. Each type of pairwise constraint applies a penalty function when the constraint is violated. The objective function of PCK-Means is to 1) choose

partitions that minimize the penalty cost of each constraint, and 2) minimize the sum of the square distance between the points and the centroids of the clusters they belong to.

More formally, let \mathcal{M} be a list of Must-Link constraint, which includes tuples of lectures (L_i, L_j) that needs to be clustered together. Let \mathcal{C} be a list of Cannot-Link constraint. Each item in \mathcal{C} is a lecture pair of the form (L_i, L_j) where lecture L_i and L_j should not be in same cluster. Each tuple in \mathcal{M} and \mathcal{C} is order-independent. Assume $W = \{w_{i,j}\}$ and $\bar{W} = \{\bar{w}_{i,j}\}$ are the sets of penalty costs of violating the **Must-Link** and **Cannot-Link** constraints respectively. Each lecture L_i is assigned to a cluster \mathcal{S}_i , where $\mathcal{S}_i \in \{h\}_{h=1}^{|V|}$, by minimizing both the distance between L_i and the cluster centroid $\mu_{\mathcal{S}_i}$ and the penalty costs of violating the constraints. The objective function of PCK-Means algorithm is as follow:

$$\begin{aligned} \mathcal{J}_{pckm} = & \frac{1}{2} \sum_{L_i \in X} \|L_i - \mu_{\mathcal{S}_i}\|^2 \\ & + \sum_{(L_i, L_j) \in \mathcal{M}} w_{ij} \mathbb{1}[\mathcal{S}_i \neq \mathcal{S}_j] + \sum_{(L_i, L_j) \in \mathcal{C}} \bar{w}_{ij} \mathbb{1}[\mathcal{S}_i = \mathcal{S}_j] \quad (1) \end{aligned}$$

The first part of the objective function is K-Means objective function while the second and the third parts are the accumulated penalty costs of violating the Must-Link and Cannot-Link constraints respectively. The $\mathbb{1}[\cdot]$ is the indicator function where $\mathbb{1}[true] = 1$ and $\mathbb{1}[false] = 0$.

In the initialization step of PCK-Means, examples of the pairwise constraints are used to estimate the centroids of clusters. Before initializing the cluster centroids, PCK-Means finds the transitive closure of tuples in Must-Link constraint and appends them to the list of Must-Link constraints. Then the updated list is used to create λ neighborhood sets. For each pair of neighborhoods, P_i and P_j with at least one pair of points that appear in the Cannot-Link list, PCK-means generates Cannot-Link constraint tuples between every pair of points in P_i and P_j and appends these tuples to the Cannot-Link constraints. Then the algorithm gets λ neighborhoods where links of type Must-Link constraint connect points within each neighborhood, and links of type Cannot-Link constraint connect some neighborhoods. If λ is higher than the number of clusters, $\lambda > |V|$, then the algorithm chooses the neighborhood sets with the largest number of instances to initialize the clusters and the centroids of each cluster. In contrast, if λ is less than the number of clusters, $\lambda < |V|$, then PCK-Means initializes the clusters from the λ neighborhoods and looks for a point that has links of type Cannot-Link constraint to all the λ neighborhoods. If so, it initializes a new $\lambda + 1$ cluster from this point. Otherwise, PCK-Means chooses the remaining $|V| - \lambda$ clusters randomly.

In general, the PCK-Means clustering algorithm is an iterative algorithm where it starts by using the pairwise constraints to initialize the clusters. Then, iteratively (1) assign points (or lectures) to clusters that minimize the combined objective function and then (2) re-estimate the centroids of each cluster according to the cluster assignment of each point. These two steps are repeated until the algorithm converges. For more information about the algorithm, please refer to [3].

6.2 Pairwise Constraints

To build the precedence graph, we use Must-Link and Cannot-Link constraints to guide the clustering process. Must-Link constraint

includes a list of pairs of lectures that have higher chance to be similar while Cannot-Link constraint contains a list of lecture pairs that have lower chance to be part of the same clusters such as lectures from the same course. Yet, the question is how to find good examples of lecture pairs for the lists of Must-Link and Cannot-Link constraints.

6.2.1 Must-Link Constraint

As our goal is to capture the content similarity between lectures across courses, we want to feed the algorithm with similar lectures from different courses that have higher chance to be part of the same cluster as examples of Must-Link instances. To do that, we can use the cosine similarity measure to calculate the similarity score between lectures from different courses and choose lecture pairs with a similarity score exceeds some predefined threshold.

Besides Similar lectures across courses, some similar lectures within the same course can be good examples of Must-Link instances. Adjacent lectures can have very similar content and hence they should be grouped together in the same cluster. For instance, the two adjacent lectures “K-Means Algorithm” and “Initialization of K-Means Clustering” have similar content as they talked about *K-Means Clustering Algorithm* and thus they need to be grouped together. Therefore, we add adjacent lectures that have a similarity score greater than the predefined threshold.

We propose two approaches to capture the similarity between lectures within courses or among courses. First, we use the cosine similarity between two lectures represented by lecture transcripts. Pairs of lectures are considered similar when they have similar content and hence the cosine similarity score would be high. Second, we use the cosine similarity between two lectures represented by lecture titles. We believe that two lectures are similar when they have very similar titles even when there are some variations in the content. One reason is that instructors sometimes explain the topic from different perspectives. For instance, one instructor might explain the lecture with a title “K-Means Clustering Algorithm” by using examples while another instructor might explain the same lecture by illustrating the theory behind it. Although the content is different, both lectures explain the same topic but from different perspectives. Another reason of using lecture titles is due to the average length of lectures in MOOCs. Lectures in MOOCs are usually shorter in length compared with regular university classes. As a result, some instructors split the topic into two or more lectures. Usually these lectures have very similar titles and should be clustered together even if their content might vary. Therefore, we decided to utilize lecture titles to measure the similarity between lectures in addition to lecture transcripts. However, we use two different predefined thresholds K_1 and K_2 to capture the lectures similarity using titles and transcripts respectively as we have to set a higher threshold for titles to minimize the noise.

In general, the list of Must-Link constraint contains any similar lectures across courses and similar adjacent lectures within courses.

6.2.2 Cannot-Link Constraint

Unlike the Must-Link constraint, Cannot-Link constraint is used to indicate lecture pairs that should not be part of the same clusters. Since we want to force the clustering algorithm to capture the similarity between lectures across courses, we add lecture pairs from the same course to the list of Cannot-Link constraint. However, not any pair can be added to the list as some adjacent lectures can have similar content or similar titles and hence need to be grouped into the same cluster. Therefore, to determine lecture pairs that are

suitable to be examples of Cannot-Link constraint, we apply the cosine similarity on the transcripts of two adjacent lectures. When the cosine similarity of two adjacent lectures, L_{ij} and $L_{i(j+1)}$ of course C_i , are less than a predefined threshold K_3 , then we can say that there is a **topic shift** and hence we can add these two adjacent lectures to the list of Cannot-Link constraint. However, before adding any lecture pairs to the list of Cannot-Link constraint, we need to ensure that the pair is not part of the Must-Link constraint and its transitive closure list. In addition to adding the two adjacent lectures L_{ij} and $L_{i(j+1)}$, we also pair the lecture L_{ij} with all the subsequent lectures of lecture $L_{i(j+1)}$ since there is a shift in the topic. As a result, we add the lectures $(L_{ij}, L_{i(j+z)})$ where $1 < z < |C_i| - j$, to the list of Cannot-Link constraint if they are not part of the Must-Link constraint and its transitive closure list.

In general, the purpose of Cannot-Link constraint is to restrict the clustering algorithm from clustering lectures within courses in order to capture the similarity between different courses. As a result, by using Must-Link and Cannot-Link constraints, the clustering algorithm learns to cluster lectures from across courses and only cluster adjacent lectures within the same course if they are similar.

7. BUILDING PRECEDENCE GRAPH

Building the precedence graph from similar MOOCs has three steps: (1) Cluster similar lectures to construct the node of the graph, (2) Link the nodes by a directed weighted edge to determine the precedence relations between nodes, and (3) Represent each node by dominant and salient terms mined from lectures belong to each nodes. In the previous section, we explain how we cluster similar lectures using PCK-Means algorithm with our proposed Must-Link and Cannot-Link constraints. In this section, we first present our method of linking the precedence graph nodes before illustrating our approach of labeling each node.

7.1 Linking Clusters

After clustering similar lectures, we need to link the scattered clusters to construct the precedence graph. As we mentioned earlier, we utilize lecture sequences in each course. We can think of the sequence of lectures in MOOCs as implicit prerequisite relationships between lectures as these sequences are carefully designed by experts. When instructors design courses, they usually maintain the prerequisite order constraints between lectures by placing prerequisite lectures before the dependent lectures. In addition, according to the *locality of references* property [1], when designing a course plan, a dependent lecture should appear as soon as possible after the prerequisite lecture to reduce students comprehension burden. Therefore, tackling the various sequence orders of lectures from different courses helps in linking clusters of lectures from across courses and thus captures the precedence relations between clusters.

To link the scattered clusters, we use the precedence relations between adjacent lectures to infer the precedence relations between clusters. If two adjacent lectures L_{ij} and $L_{i(j+1)}$ of course C_i appear in two different clusters, then these two clusters need to be linked by an edge with a direction from the cluster that includes lecture L_{ij} to the cluster that has lecture $L_{i(j+1)}$. Sometimes some adjacent lectures appear in the same cluster and hence we ignore the sequence relation of these lectures.

To capture the strength of the precedence relations between clusters, and hence how these relations are common in current MOOCs, we attach each edge with different weights. We accumulate the frequency of courses that have adjacent lectures clustered into two different

clusters to determine the weight between these two clusters. The equation to determine the edge weight is as follow:

$$W(\mathcal{S}_i \rightarrow \mathcal{S}_j) = \sum_{\forall C \in X} \sum_{z=1}^{|C|-1} \mathbb{1}[L_z \in \mathcal{S}_i \wedge L_{z+1} \in \mathcal{S}_j] \quad (2)$$

where $W(\mathcal{S}_i \rightarrow \mathcal{S}_j)$ is the weight of the edge between cluster \mathcal{S}_i and \mathcal{S}_j and $\mathbb{1}[\cdot]$ is an indicator function where $\mathbb{1}[true] = 1$ and $\mathbb{1}[false] = 0$.

Since the edge weights determine the popularity of relations across similar courses, edge weights are not normalized to be between 0 and 1 because normalization will produce misleading weights. For example, if we use normalized edge weights, then the edge that connects two clusters that have adjacent lectures from one course will have the same weight; which is equal to 1, to the edge that connects two clusters that have adjacent lectures from N courses. Therefore, we use unnormalized edge weights to capture the popularity of the precedence relations.

7.2 Labeling Clusters

Each node in the precedence graph is labeled by some key terms to represent the topics or key concepts discussed by the lectures attached to this node. To extract the key terms from lectures, we exploit lecture titles and transcripts represented by bag-of-words and TF-IDF representations respectively. Lecture titles are very concise and usually have the key terms in lectures. On the other hand, lecture transcripts are more elaborative and would help in extracting other important key terms that demonstrate topics or key concepts of each cluster.

The basic idea to extract the key terms is to accumulate the vector representations of each lecture that belongs to the same cluster in order to find the key terms of that cluster. In other words, for all lectures that belong to the same cluster we accumulate the bag-of-word representation vectors of their titles and also add the TF-IDF weighting vectors of their transcripts. Then, we use the top k terms from these two different representations to find the salient terms that represent each cluster. The following is the equation used to specify the key words of each cluster:

$$Label(\mathcal{S}_i) = \left(\max_k \sum_{j=1}^{|D|} \sum_{\forall L \in \mathcal{S}_i} TFIDF(w_j | w_j \in d_L) \right) \cup \left(\max_k \sum_{j=1}^{|T|} \sum_{\forall L \in \mathcal{S}_i} BOW(w_j | w_j \in t_L) \right) \quad (3)$$

where the first part finds the top k terms by using the TF-IDF representation of lecture transcripts d_L where $|D|$ is the total number of vocabularies in the corpus of lecture transcripts. For each word w_j in the vocabulary, we accumulate the TF-IDF weights of word w_j if the word appears in lecture L that belongs to cluster \mathcal{S}_i . Similarly, the second part determines the top k terms by exploiting the bag-of-words representation of titles t_L where the total number of vocabularies in lecture titles is $|T|$. We also accumulate the BOW weights of each word belongs to titles of all lectures that are part of

cluster \mathcal{S}_i . By taking the union of these two sets of top words, we extract salient terms that clearly explain the content of each clusters.

8. EVALUATION

In this section, we evaluate the performance of our approach for clustering similar lectures using PCK-Means algorithm with the proposed pairwise constraints. We first present the dataset and ground truth we used in our evaluation. Then, we compare the performance of the clustering algorithms using both representations: word counts (sparse representation) and embeddings (dense representation). We also present some examples of the learning paths extracted from the precedence graph that was constructed by our approach. Finally, we discuss some limitations of our study.

8.1 Datasets

We used a dataset of six modules related to *Unsupervised Learning* and *Clustering Algorithms* from five real machine learning and data mining courses offered by the Coursera platform². These modules include “Unsupervised Machine Learning”, “Partitioning Based Clustering Methods and Hierarchical Clustering Methods”, “Unsupervised Learning”, “Clustering”, “Clustering With K-Means”, and “Hierarchical Clustering” (see Table 1.) The total number of lectures in the dataset is 65 lectures. Each lecture is represented by its title and transcript.

To evaluate the performance of the PCK-Means algorithm and the effectiveness of the proposed constraints, we asked experts to construct the ground truth labels of our dataset. Each of our four experts (a Machine Learning professor, an Information Science professor, a Machine Learning graduate student, and a Database and Information Systems graduate student) manually grouped lectures based on topics similarities. None of the experts is participating in this study.

To measure the level of agreement among our experts, we used the Fleiss’ kappa measure. Fleiss’ Kappa is a statistical measure of inter-rater agreement used to determine the level of agreement between two or more raters. The kappa score of labels collected from experts was $\kappa = 0.65$, which indicates substantial agreements between the annotators.

After receiving the labeled datasets from our experts, we used the majority votes to decide the cluster assignment of each lecture. For lectures that experts disagreed on their clustering assignment, we decided to follow the advice of our experts and created a new cluster for each lecture. The total number of labeled clusters was 21 clusters.

8.2 Clustering Performance

To evaluate the performance of our clustering approach and to study the effect of using the pairwise constraints on clustering performance, we compared the PCK-Means algorithm to the standard K-Means algorithm. In particular, we focused on two measures: (1) Adjusted Mutual Information (AMI), and (2) Fowlkes-Mallows scores (FMI). Adjusted Mutual Information is a variation of the Mutual Information measure that is used for comparing clustering results. According to

Machine Learning ⁵	Unsupervised Learning	12
Machine Learning With Python ⁶	Clustering	6
Machine Learning Clustering and Retrieval ⁷	Clustering With K-Means	13
	Hierarchical Clustering	6

Romano et al. [17], AMI measure should be used to evaluate the clustering performance when the reference clustering is unbalanced and contain small clusters. Since we have unbalanced clusters (i.e., some clusters have many lectures while others have one or two lectures), we decided to use AMI for the evaluation. The second metric, Fowlkes-Mallows scores, is a geometric mean of precision and recall where precision determines the correctness of the clustering assignments of lectures while recall measures the completeness of the assignments. Similar to AMI, FMI gives a zero score for random clustering assignments.

Before discussing clustering performance, it worth mentioning that for finding the lists of Must-Link and Cannot-Link constraints, we tried various values for each threshold, K_1 , K_2 , and K_3 , and used the values that gave the highest performance. For TF-IDF and BOW representations, the thresholds were $K_1 = 0.85$, $K_2 = 0.3$, and $K_3 = 0.07$ for titles and transcripts in Must-Link list and for transcript in Cannot-Link list respectively. For the uSIF representation, the thresholds were $K_1 = 0.85$, $K_2 = 0.65$, and $K_3 = 0$. Having $K_3 = 0$ in uSIF representation does not mean that we exclude the list of Cannot-Link constraint. The cosine similarity values in the uSIF embedding representation can have negative values as some values in the embedding vectors are negatives.

Because PCK-Means and K-Means algorithms produce different clustering assignments for each run (based on how the centroids are initialized), we ran each clustering algorithm 20 times. Then we recorded the average and the max scores. TF-IDF and bag-of-words representations have a total number of 1650 dimension features. So, we reduced the number of dimensions before clustering the data by applying the T-distributed Stochastic Neighbor Embedding (t-SNE) algorithm[12]. We also applied the t-SNE reduction technique on the uSIF embedding. However, because the performance of the uSIF was degraded due to the dimensions reduction, we decided to use all 200 dimensions for the embedding representation: 100 for titles, and 100 for transcripts. Table 2 summarizes the results.

The average and max scores for each algorithm are presented in Table 2. We can see from the table that PCK-Means outperforms K-Means in both representations. The differences in performance between PCK-Means and K-Means are statistically significant, using Welch's t-test, with p-value score < 0.01 in TF-IDF\BOW and

Table 2: The performance of clustering algorithms. PCK-Means outperforms the standard K-Means in both representations: (1) TF-IDF for lecture transcripts and bag-of-words (BOW) for lecture titles, (2) The embedding representation (uSIF) for both lecture transcripts and titles. The performance of PCK-Means is statistically significant (represented by *) in both representations.

Method	AMI		FMI	
	Average	Max	Average	Max
TF-IDF\BOW Representation				
K-Means	0.523	0.597	0.412	0.478
PCK-Means	0.551*	0.649	0.511*	0.632
Embedding Representation (uSIF)				
K-Means	0.395	0.491	0.344	0.452
PCK-Means	0.480*	0.536	0.420*	0.548

uSIF representations for FMI measure. In contrast, when using AMI for the comparison, the differences between PCK-Means and K-Means are statistically significant with p-value scores < 0.01 with uSIF representation and p-value < 0.05 with TF-IDF\BOW representation. We also compare the performance of PCK-Means using different representations: TF-IDF\BOW and uSIF. It is clear from the table that PCK-Means with TF-IDF\BOW representation outperforms PCK-Means with uSIF embedding representation where the difference is statistically significant with p-value < 0.01 in both AMI and FMI measures. In general, PCK-Means with TF-IDF\BOW representation achieves the highest performance.

Since uSIF embedding representation uses pretrained word embeddings that allow it to capture the semantic similarity between documents, we expected it to have the highest performance. However, it did not perform as expected. We investigate this issue and found that some words from our dataset of lecture transcripts and titles do not exist in the list of words from the Glove pretrained model. The total number of missing words was 31 words from both lecture titles and transcripts. The missing words includes some key terms, such as *agglomerative*, *dendrogram*, *subcluster*, *medoids*, *sparkml*, and *dbscan*.

To study the effect of using the lecture titles and transcripts when generating the Must-Link constraint, we compared the performance of the PCK-Means algorithm using only Must-link constraint from titles to the performance of the same algorithm using only Must-link constraint from transcripts. We use TF-IDF and bag-of-words representation with the same set of thresholds for the comparison as PCK-Means achieves the highest performance with this representation. We show the results of this experiment in Table 3. The results indicate that using both lecture titles and transcripts to produce the Must-Link constraint achieves the highest score. We conclude that title and transcripts representations are important for capturing the similarity between lectures. We also notice that removing Must-Link tuples of lecture transcripts reduces the clustering performance more than removing title tuples. This is expected as lecture transcripts contain more keywords than titles. However, using only titles to generate the Must-Link constraint tuples achieves comparable results, which also indicates the importance of using titles to capture lectures similarities.

Table 3: The performance of the clustering in PCK-Means, PCK-No-Title, and PCK-No-Trans using TF-IDF \BOW representation. In PCK-No-Title, we remove all the tuples from Must-Link list that are generated by using lecture titles. In PCK-No-Trans, all Must-Link tuples produced by lecture transcript are removed. Combining both titles and transcripts improves the performance of PCK-Means.

Method	AMI		FMI	
	Average	Max	Average	Max
PCK-Means	0.551	0.649	0.511	0.632
PCK-No-Title	0.534	0.561	0.489	0.576
PCK-No-Trans	0.486	0.559	0.403	0.489

8.3 Examples of Learning Paths

After clustering lectures, we create the precedence graph that represents the six modules by linking the clusters and labeling them with salient terms. We utilize the clusters generated by PCK-Means algorithm with TF-IDF and bag-of-words representation as it achieves the highest performance. In this section, we present several learning paths examples extracted from our precedence graph.

Follow the crowd: The first example we extracted from our precedence graph is the learning path that is shared across many modules in our dataset. Students who follow the most common learning path would have a good overview of the topic as they follow the most popular path that is shared by many courses. Figure 4 depicts the common learning path for the *Unsupervised Learning* topic. The figure shows that the learning path starts with an introduction about Unsupervised Learning, followed by k-Means clustering algorithm and how to choose the number of clusters. Then, dimensionality reduction in clustering is discussed next using the Principle Component Analysis algorithm as an example of dimensionality reduction techniques.

The expert learning path: The second example path we extracted from the precedence graph is one of the longest learning paths. Figure 5 shows a path that spans over seven nodes. This path starts with the partitioning-based clustering methods discussing algorithms, such as “K-Means”, “K-Medians”, “K-Medoids”, and “K-Modes”. It then discusses the application of “K-Means Algorithm” in apache sparkml. Next, it shifts to the hierarchical clustering methods by recommending “Divisive Clustering Algorithm” and “Agglomerative Clustering”. Finally, it presents the “DBSCAN”, a density-based clustering algorithms. This long path is more comprehensive than the common path as it explores more clustering algorithms. Students who are interested in gaining comprehensive knowledge about clustering will find this path very rewarding. Note that such a path does not exist in any of the original six modules we have in our dataset; but it was extracted from the precedence graph constructed by our approach.

Give me some options: Figure 6 shows an example of a sub-graph with several alternative learning paths. To learn the “K-Means” concept, a student can either start with introduction to unsupervised learning or learn about partitioning-based clustering methods. After learning “K-Means”, the student can choose one of the four possible paths: (1) Learn how to choose the number of clusters using “Elbow” methods, (2) Learn about different partitioning algorithms such as “K-Medians”, (3) Move to the hierarchical clustering algorithms and learn “Divisive Algorithm”, or (4) Shift to the hierarchical clustering algorithms and learn “Agglomerative clustering”. Each of these

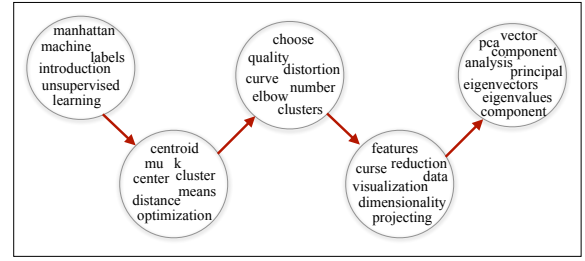

Figure 4: The common learning path extracted from the Precedence Graph. This path is shared by many modules and includes fundamental concepts in Unsupervised Learning topic.

Figure 5: An example of a long learning path extracted from the Precedence Graph. This long path can support students who acquiring expert knowledge as it presents many clustering algorithms.

possible paths are also precedence to other nodes as shown in Figure 6. From the sub-graph, students can choose the learning path that fits their needs. Additionally, the sub-graph shown in Figure 6 gives students a comprehensive overview of how concepts are connected among several courses related to the *Unsupervised Learning* topic.

8.4 Limitations

There are two limitations of our study. First, using the sequence relations among lectures to infer the precedence relations between clusters can cause cycles in the precedence graph. The method proposed in this paper has not addressed the problem of cycles. The naive approach to solve the problem of cycles is to eliminate edges with lower weights that cause cycles in the graph. Further investigation for addressing graph cycles is left as a future work.

Second, in the evaluation we have not examined the performance of our approach in other domains. In the future work, we plan to apply our method on courses from different domain areas and thus generate the precedence graph for each domain.

9. CONCLUSIONS

In this paper, we developed an approach to build the precedence graph of similar MOOCs that have overlaps in content. Our approach is based on Pairwise Constrained K-Means (PCK-Means) clustering algorithm that incorporates constraints to guide the clustering process to focus on clustering similar lectures across courses. We proposed a method of generating the lists of Must-Link and Cannot-Link constraints. PCK-Means with our generated constraint examples significantly outperforms the standard K-Means algorithm with the TF-IDF and bag-of-words representations achieves the highest performance. Using the clusters of similar lectures as nodes in the precedence graph, we connect each cluster according to the

Figure 6: An example of a sub-graph extracted from the Precedence Graph. It depicts some possible paths to learn the topic. It also gives a comprehensive overview about the topic.

precedence relations between lectures in various courses by directed weighted edges to reflect the strength of the precedence relations between clusters. Finally, we label each node in the precedence graph by key concepts extracted from lectures belonging to each cluster. The generated precedence graph reveals popular learning paths as well as alternative learning paths of learning the topics of MOOCs in our dataset.

The precedence graph constructed by our approach is considered the initial block for building applications that support personalized learning. As an example, we can use the precedence graph to build a tool that visualizes the precedence graph to help learners to choose the desired learning paths that are suitable to their interests and backgrounds. Another application is to build a tool that recommends personalized study plans for students based on their interests and time constraints. As discussed in [9, 7], the main obstacle that faces online learners is not having enough time for the course. Further, according to [24, 22], some learners register for a MOOC with a motivation to learn some concepts and hence they drop the course after they are done with studying the concepts of their interest. Wilkowski et al. [22] found that large groups of learners just wanted to learn some concepts without the purpose of earning certificates. Therefore, it is very important to build an application that recommends study plans based on learners motivation, interests, and time constraints. Our proposed precedence graph would be the initial step for building such applications.

10. ACKNOWLEDGMENTS

We would like to thanks all the four participants in the user study for their time and effort to label the dataset.

ABSTRACT

Effectively estimating student enrollment and recruiting students is critical to the success of any university. However, despite having an abundance of data and researchers at the forefront of data science, traditional universities are not fully leveraging machine learning and data mining approaches to improve their enrollment management strategies. In this project, we use data at a large, public university to increase their student enrollment. We do this by first predicting the enrollment of admitted first-year, first-time students using a suite of machine learning classifiers (AUROC = 0.85). We then use the results from these machine learning experiments in conjunction with genetic algorithms to optimize scholarship disbursement. We show the effectiveness of this approach using real-world enrollment metrics. Our optimized model was expected to increase enrollment yield by 15.8% over previous disbursement strategies. After deploying the model and confirming student enrollment decisions, the university actually saw a 23.3% increase in enrollment yield. This resulted in millions of dollars in additional annual tuition revenue and a commitment by the university to employ the method in subsequent enrollment cycles. We see this as a successful case study of how educational institutions can more effectively leverage their data.

Keywords

education, funding, tuition, enrollment management, financial aid

1. INTRODUCTION

Managing student enrollment is one of the core administrative tasks of any university. However, it is far from simple as universities aim to attract and retain the best students with limited resources [4, 10]. Enrollment management has wide-ranging implications on institutions' student body composition as well as their budgeting and finances, where a reliance on tuition income necessitates accurately forecasting

student enrollments [9, 23]. One instrument that has continually been leveraged in the pursuit of enrollments and the associated tuition income is financial aid as receiving a financial aid award increases the likelihood of a student enrolling at the award-giving institution [13, 10]. While financial aid remains a powerful mechanism for institutions to reach their admissions and revenue targets, miscalculating projected student enrollments and mismanaging financial aid funds can have severe implications (such as rescinding over-committed offers¹) [2]. Furthermore, as institutions face tightening budgets and find their pricing policies continually under scrutiny, it remains imperative for them to optimize the resources they have by maximizing enrollments and the associated tuition revenue from financial aid programs [8, 12]. As such, accurately predicting enrollment and optimizing how student aid is disbursed is critical to enrollment management with financial implications that cascade across the entirety of an institution. In this work, we developed an approach to address this challenge, implemented it for a recent entering class, and found that it far outperformed previous strategies.

Predicting enrollment and optimizing the allocation of student aid requires data on student admissions and operational budgets. This data is stored in institutions' organizational databases or can be extracted from operational records. However, despite having this data on previous enrollments and finances, institutions are often slow to leverage it to gain actionable insights and improve institutional processes [20, 26, 14]. What's more, using data for insights in education is less prevalent at traditional campuses (i.e. schools where learning is primarily on-campus) and more common in online and computerized environments, which are more amenable to the collection and analysis of digitized data [17]. To this end, traditional universities remain "data-rich" but are "information-poor" in that they have the raw data needed to extract intelligible insights but are unable to do so due to infrastructure limitations and untrained personnel, among other reasons [21]. This results in the outsourcing of data-centric enrollment work (including developing scholarship disbursement and enrollment strategies) to full-service consulting firms, which do not disclose their proprietary approaches or how their results are evaluated [11]. The lack of motivation for consulting services to disseminate their work coupled with institutions trying to maintain competitive advantages in recruitment limits the extent of

published research on how institutions can utilize data to improve recruitment processes. As a result, this dearth of literature provides little to demonstrate how data mining and machine learning can assist in the critical mission of enrollment management and in allocating financial aid.

In this project, we mine data from a large, public university in the United States (US) to optimize the disbursement of a merit-based scholarship for domestic non-resident students. We do this in two broad steps. In the first step, we create a predictive model of student enrollment using historical student application data. In the second step, we use a genetic algorithm to optimize scholarship disbursement to maximize student enrollment based on the predictive enrollment model from steps. We conducted this work during a recent admissions cycle of the university and the optimized awards were given to a recent entering class. After seeing improvement in student enrollment yield and an increase of millions of dollars in annual tuition revenue, the university incorporated our approach into their enrollment management process. We believe this project is a case study for other institutions seeking to similarly leverage institutional data for improving enrollment forecasting and financial aid allocation.

2. RELEVANT WORK

The following discussion of relevant work is not exhaustive but is intended to give examples of relevant approaches with a focus on more recent work. While there is some work showing how to predict enrollment, there is very little showing how to allocate scholarships and hardly anything that ties the two together.

2.1 Predicting Enrollment

A few studies have employed machine learning and data mining techniques to predict university enrollment using non-neural approaches. DesJardins developed a logistic regression model using a dataset of approximately 14,400 students from an undisclosed tier I research university in the US. DesJardins' model gave an area under the receiver operating characteristic curve (AUROC) of 0.72 when predicting whether or not a student will enroll [5]. Similarly, Goenner and Paul used logistic regression to predict which of over 15,000 students at a large US university would eventually enroll [7]. Their predictive model gave an AUROC value of 0.87. Nandeshwar and Chaudhari used a suite of learners to predict which of approximately 28,000 students would enroll at West Virginia University [16]. They were interested in variables contributing to students' decisions (finding financial aid to be an important factor) and did not give an assessment of how well their models fared outside of accuracy (which was about 84%).

In addition to the above studies examining non-neural approaches for predicting enrollment, studies have also found that neural approaches fare very well for the same task and often perform better than non-neural approaches. For example, Walczak evaluated different neural network designs when predicting student enrollment at a US liberal arts college, stressing the problem as one of resource allocation [24]. Using a few thousand students, Walczak found that back-propagating neural networks fared best among those compared. Walczak and Sicich later compared neural networks

versus logistic regression to predict enrollment at two US universities [25], finding that neural networks performed better than logistic regression. Chang used logistic regression, decision trees, and neural networks to predict the enrollment of applicants at an undisclosed university, also finding that neural networks outperformed other models when judging by classification accuracy [3].

2.2 Scholarship Optimization

While there are some examples of works examining the use of machine learning in predicting enrollment, there is very little detailing scholarship disbursement strategies, especially ones leveraging machine learning and/or numerical optimization techniques. One example is the work of Alhassan and Lawal, who demonstrated the use of tree-based models for determining which students would be awarded scholarships in Nigeria [1]. Alhassan and Lawal describe the results as "effective" compared to approaches previously used but did not provide additional insight on the success of their approach. Spaulding and Olswang demonstrated the use of discriminant analysis to model the enrollment decisions of students based on varying need-based financial aid awards at an undisclosed university in the US [22]. They found that changes in their award policy would yield only small upticks in enrollment.

One work used machine learning to predict enrollment in conjunction with a numerical optimization technique to disburse scholarships. Sarafraz et al. used neural networks with genetic algorithms to optimize financial aid allocations and while our research is similar in spirit, there are a few notable differences [19]. Firstly, the scholarship fund optimized in this work is merit-based, meaning there are upper and lower bounds on scholarship awards that are specific to each student. This makes for a more difficult optimization task. We also examine alternative predictive models beyond just neural networks (such as ensemble approaches) and use a larger dataset in terms of both the number of observations (i.e. students) and the number of features (over 72,000 observations vs 4,082; over 100 features vs 6). We also provide a comprehensive description of final model performance across multiple metrics and a detailed outline of how genetic algorithms can be used for aid disbursement, including a binning framework to drive the optimization task. Finally, we share real-world enrollment metrics after employing the scholarship optimization to demonstrate the effectiveness of our approach.

3. METHODS

We present the methods for this work by first giving an overview of the setting; then, we describe the data and feature engineering; we then discuss how we predicted enrollment; finally, we discuss optimization constraints and the optimization process. The overall process for this work is shown in Figure 1. Due to the sensitive nature of the data and the fact that it contains personally identifiable information (i.e. student names, addresses, and high schools), we are unable to make it widely available. However, we present the methods below with as much transparency as we can to allow others to replicate the work. We used the Python programming language and implemented feature engineering and predictions using pandas and sci-kit learn, re-

spectively [18]. We developed genetic algorithms using Distributed Evolutionary Algorithms in Python (DEAP) [6].

3.1 Setting

This scholarship optimization work was performed at a large, public US University (the University²). The scholarship fund examined was created to maintain the University’s academic standards while maximizing the enrollment of first-time, first-year (freshmen) domestic non-resident (DNR) students by giving them financial incentive to attend the University. DNR students are students from the US who are not from the state in which the University is located. DNR students account for larger tuition charges than their resident counterparts so their enrollment is of high importance from a budgeting perspective. Tens of millions of dollars in total are awarded annually to these students from the scholarship fund with millions eventually given to students who enroll.

The University is on a quarter-based term system and a vast majority of incoming freshman students start in the fall after applying during the preceding fall and being notified of their acceptance in the preceding spring. The scholarship fund (henceforth referred to as the “DNR scholarships” for domestic non-resident scholarships) was designated to be disbursed for equal amounts across three academic quarters for each of four years (12 quarters total). The DNR scholarships were to be disbursed based on merit. As such, students with higher academic profiles, as defined later, were given equal or larger scholarships than those with lower academic profiles, regardless of financial need. Additionally, only freshmen DNR students who were accepted to the University were eligible for a DNR scholarship award. All admitted DNR students were automatically considered for a DNR scholarship and students did not need to apply for the scholarship.

In years prior, the disbursement strategies for the DNR scholarship were developed by external consulting services. Starting in 2018, the disbursement strategy was brought under the technical stewardship of the University. The first application cycle under the stewardship of the University (i.e. the fall 2018 entering class) is the application cycle for which we optimized scholarship disbursement and detail in this writing. The models that were previously developed for the disbursement of the scholarship fund were proprietary to the consulting services and could not be leveraged. However, student application, enrollment, and scholarship data from prior years was available. When describing results, we compare the results from our approach to that developed by the consulting services. We cannot compare the approach detailed in this writing to a completely un-optimized approach or one that is randomized because the scholarship has never been disbursed in such a manner.

Award-receiving students concurrently learned of the amount of their scholarship and of their admittance to the University. However, not all applications were scored by admissions officers when the first awards were given to students. This was primarily due to the admissions review timeline at the University. As such, we did not know of every admit-

²University administrative offices requested that the institution not be identified.

ted student at the time of optimization yet the scholarship awards were only to be given to admitted students. Thus, the 2018 entering class’s data could not be used directly in the optimizations. Instead, we used data from prior years to develop a fund allocation strategy and then applied this strategy when disbursing scholarships to the 2018 entering class. This was with the expectation that applicants in the 2018 applicant pool were statistically similar to years prior across all the variables used in the modeling and we checked to ensure that this was in fact the case using individual t-tests.

3.2 Data

The data for this work consisted of information on all freshmen DNR applicants to the University from 2014-2017 with usable data. This totaled 72,589 students. The data was compiled from two major institutional sources: the students’ admissions applications and their Free Application for Federal Student Aid (FAFSA) information. The FAFSA is an application prepared by incoming and current US college students to determine their eligibility for financial aid. Examples of data from students’ admissions applications include their high school coursework, entrance exam scores, college GPA (if they had taken classes for credit), whether they were a first-generation college student, and their parents’ educational attainment. These were all self-reported and verified by the University as needed. Data directly from and derived from student FAFSA filings included students’ family income, their expected family contribution to college expenses (as calculated by the University), and loan amounts awarded to the student. About 66% of students had filled a FAFSA. Also included in the data were indicators of whether each student eventually enrolled at the University. Of the 72,589 students in the dataset, 5,081 enrolled (7.00% of all). Demographic variables such as gender and race were available but were not used as discussed in Section 4.1.

The data included tuition amounts students would pay on an annual basis, their financial aid grants and scholarships awarded (outside of DNR scholarship awards), and their DNR scholarship award amount. These variables were not included in any prediction or optimization model on their own. Instead, we created a “`reduced_tuition`” variable which was the annual tuition amount for the students less their total grants and scholarships (i.e. the other two variables summed). We used this variable as a single financial aid and tuition-related feature for the optimization process. This feature is not altered when developing the predictive classifier but is altered during the optimization task, during which the response of students to different award amounts are simulated.

3.3 Feature Engineering

Prior to prediction and optimization, we engineered features from existing variables. First, we either converted categorical variables to dummy variables or replaced them with a binary indicator variable. Then, we grouped students based on their FAFSA award amounts into 6 discrete bins (which were in line with University financial aid record-keeping), each of which was used as a categorical feature. We created binary indications of whether students attended each of the 10 most popular high schools for student applications

Figure 1: Process for optimizing scholarships, starting with data from institutional databases and ending with disbursements.

and did the same for the 10 most popular states from which students applied. A binary indication was also created for a student athlete designation as each sport had its own application codes. In addition, we also created a separate binary indication for whether the student was transferring any credits from a college in high school program. Students also indicated their academic interests on their applications to the University. We pulled these from their applications and grouped them into 12 broader categories based primarily on the college/department they were associated with at the University (e.g. “Engineering”, “Humanities”, “Health Sciences”, etc.). We then created binary indications of whether a student was interested in each of the categories. Only students’ first application to the University and the resulting admissions/enrollment decisions were included in the data. This ultimately resulted in a total of 108 features extracted from students’ University and FAFSA applications.

Not all applicants filed a FAFSA form and we imputed missing FAFSA-related values. We performed this imputation by building a separate gradient-boosted regression tree model for each FAFSA-related feature using all features that were complete. We then used these regression models to predict the missing values. Only FAFSA-related values were missing and no other features needed to be imputed.

3.4 Predicting Enrollment

To predict enrollment, we first randomly divided the data using a 80-20 training-test split, with 57,359 students in the training set and 14,340 students in the test set. We did not re-balance the data with respect to classes. We scaled the training data by subtracting the median of each feature and dividing by the feature’s interquartile range. We subsequently scaled the test data using the scaling values from the training data. The binary outcome variable indicating whether the student enrolled at the University was not scaled.

After performing the training-test split, we trained 7 machine learning (ML) classifiers on the training set to predict enrollment. These classifiers were: a bagging tree ensemble (BC), gradient boosted trees (XGB), K-nearest neighbors (KNN), random forests (RF), regularized logistic regression (LR), support vector machines (SVM), and a neural network with 3 hidden layers (MLP). We tuned the hyperparameters for each of the classifiers using 5-fold cross validation on the training set. We report performance from all classifiers on the test set, which was not used to train the classifiers and only used to evaluate final performance. We used the classifier with the best performance to optimize scholarship disbursement.

3.5 Optimizing Scholarships

3.5.1 Genetic Algorithms

After developing a classifier to predict enrollment, we used the predictions from the classifier as an objective function in optimization. The aim of the optimization was to develop a strategy that maximized student enrollment from the DNR scholarships. In other words, the optimized approach disbursed scholarships in a manner that maximized the number of students who would enroll at the University from a pool of admitted students to the University. In this work, we used a genetic algorithm (GA) for optimization as GAs are known to work well with a well-defined measure to optimize (i.e. student enrollment) but not a well-defined, continuous, and/or differentiable objective function. GAs are also known to find near-optimal solutions quickly, which was essential when we wanted to rapidly outline and iterate across different budgeting scenarios early in our modeling.

GAs are a class of evolutionary algorithms and are inspired by biological evolution. GAs generally involve iteratively starting with a population of chromosomes, undergoing selection across this population according to a measure of fitness, using genetic crossover and mutation to produce offspring from the most fit individuals, and then using this offspring as the population for the next iteration [15]. The overall population fitness improves with each iteration and the GA eventually converges towards an optimal solution. In this work, we start with a population of award disbursement strategies whose “genetic material” (chromosomes) are a set of scholarship award values; the measure of fitness to assess these individuals is based on predicted enrollment after accounting for constraints; and the crossover and mutation functions used to create offspring are based on altering scholarship award values.

We used the data for the 2017 admitted class in the optimization of scholarship funds. In all, this was 9,479 students (N_{total}). In this sense, we used data from the year prior to optimize the disbursement for the 2018 entering class. We pared the data used in optimizations down to a single year’s application cohort to avoid having to consider if any of the optimization constraints in Section 3.5.3 were being violated for each of the application years simultaneously.

3.5.2 Binning Students

We generated a set of possible scholarship awards that spanned S_{min} to a chosen maximum (S_{max}) in \$300 increments and included \$0. We did not determine S_{max} beforehand but instead set it such that the optimization procedure did not generate an output that included a S_{max} scholarship award. S_{min} was evenly divisible by \$300 and we generated possible scholarship awards in \$300 increments to satisfy constraint

(4) from Section 3.5.3. In all, there were over 20 unique scholarship award values and only these award values were used in the optimizations.

Part of the difficulty of this particular optimization task lies in the fact that awards were to be given in a merit-based manner. As such, the scholarship award for any student is dependent on the awards of students with similar academic profiles. For example, if one was to rank all admitted students in the application pool based on a measure of merit, the minimum possible award given to a particular student would be determined by the award given to the student with the merit that is immediately lower. Similarly, the maximum award for a particular student would be equal to the award given to the student with the merit that is immediately higher. As such, if optimizing on a per-student basis, altering the award for any given student to influence their enrollment decision could result in a cascade that subsequently effects every other student's award amount. This results in a very complex fitness landscape when optimizing scholarship awards on an individual basis.

To resolve this issue of an optimization cascade, we first ranked and then binned students based on academic merit such that all students in the same bin received the same scholarship award. To perform this binning, we sequentially ranked students based on 3 variables: their application academic score, their high school GPA, and their scores on college entrance exams, in that order. This ranking was students' "academic profile." Each student's application academic score was based on a holistic scoring of their academics and was the primary variable for determining their academic profile. We were provided this metric by the University admissions office and it was not calculated/determined by us. Ties between students having the same application academic score were broken by looking at their high school GPA; any remaining ties thereafter were broken using students' entrance exam scores. Once students were ranked, they were divided into 20 ventiles based on their academic profiles (i.e. students were grouped across every 5th percentile) with each ventile receiving the same scholarship award amount. Using ventiles allowed for us to have sufficient flexibility when exploring the fitness landscape during optimization while also not being so granular as to continually be caught in local extrema. Additionally, ventiles helped mitigate the effect of optimization cascades by giving identical awards to students with similar academic profiles. We refer to each of these ventiles as a "bin" and each bin served as the chromosomal building block for the GA. A single scholarship allocation strategy consisted of the scholarship awards across all 20 scholarship bins and is referred to as an "individual" henceforth when used in the context of the GA. Thus, each individual's genetic material can be thought of as being in the form of chromosomes composed of scholarship award bins. It should be noted that we used ventiles after examining the optimization results from other binning strategies (namely using 10, 15, and 25 bins) and finding them to give lower predicted enrollments. We did not, however, attempt to find an optimal bin number beyond this but do intend to explore this in the future.

After binning students, we created a fitness function to evaluate the effect of altering the `reduced_tuition` variable on

student enrollment. Specifically, this function took the genetic material of a scholarship individual (i.e. a set of scholarship awards for each bin) and then re-evaluated the `reduced_tuition` variable for each student based on their updated DNR scholarship award. As noted above, we created the `reduced_tuition` variable by taking the tuition due for a student and subtracting their total grants and scholarships; it was the only financial aid and tuition-related variable used in the predictive model. The function re-calculated each student's likelihood for enrollment based on the updated values for `reduced_tuition` using the predictive enrollment model. The final output for the fitness function was a calculation of the number of students predicted to enroll for a given scholarship individual, which we used as the fitness criterion for evaluating individuals.

3.5.3 Modeling Constraints

Several constraints were posed on the scholarship disbursement by University administrators. Due to University policy, exact values for awards and budgets will not be discussed. Some constraints on the disbursement strategy were as follow, where F represents funds in DNR scholarship offers, B represents funds in the DNR scholarship budget, N specifies a count of students, and S specifies a scholarship award amount:

1. The total amount spent on DNR scholarships (F_{spent}) cannot exceed a pre-determined amount (B_{spent}):

$$F_{\text{spent}} \leq B_{\text{spent}}$$
2. The total amount offered to students in DNR scholarships regardless of whether they enroll (F_{offered}) cannot exceed a pre-determined amount (B_{offered}):

$$F_{\text{offered}} \leq B_{\text{offered}}$$
3. The percentage of admitted students who are awarded scholarships ($N_{\% \text{awarded}}$) should be approximately equal to a pre-determined percentage ($N_{\% \text{target}}$):

$$N_{\% \text{awarded}} \approx N_{\% \text{target}}$$
4. The award amounts must be divisible by \$300 to allow for round hundred-dollar splits across three academic terms.
5. There is a minimum value for a single scholarship award (S_{min}) but no pre-determined maximum value.

The organization of the population, individuals, and bins for the GA optimization is shown in Figure 2. We generated an initial population of p individuals by randomly selecting K scholarship awards (one for each bin) from the set of possible scholarship awards and sorting for each individual. For this work, $p = 1000$ and $K = 20$. Each bin contained the same number of students (N_{bin}), which was equal to $\frac{N_{\text{total}}}{K}$. All students in the same bin received the same award for a given individual; awards were not unique to each bin and could be duplicated across a given individual. N_{bin} multiplied by the scholarship award value for each bin equalled the funds awarded for that respective bin; the sum of these across all K scholarship bins for an individual was F_{offered} for that individual. The predicted number of enrollees for each scholarship bin multiplied by the award for that respective bin equalled the funds spent for that bin; the sum

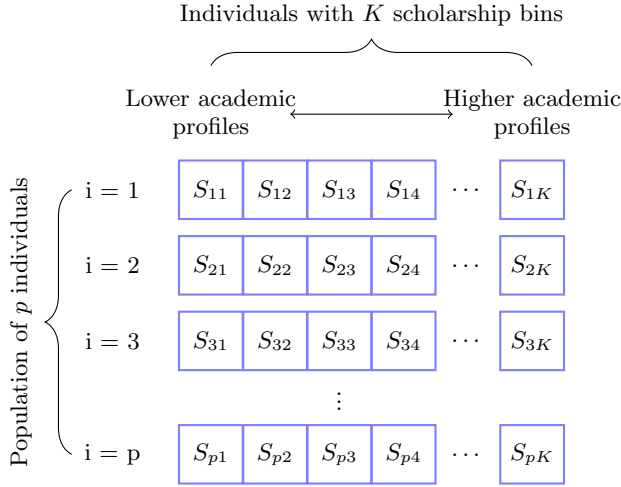

Figure 2: Genetic algorithm setup. Individuals (i) are scholarship allocation strategies of K scholarship bins (j). The population consists of p individuals. Each S_{ij} is a scholarship award value for the i^{th} individual and the j^{th} scholarship bin. The bins are sorted based on academic profile such that $S_{i1} \leq S_{i2} \leq S_{i3} \dots \leq S_{iK}$ for any given i (but not necessarily across individuals). For this work, $K = 20$ and $p = 1000$.

of these across all K scholarship bins for an individual was F_{spent} for that individual. The number of bins with non-zero award values divided by K was equal to $N_{\% \text{awarded}}$ for an individual.

We penalized each individual's fitness if the optimization constraints above were violated. We initialized a single penalty coefficient (σ) to 1.0 and then successively enforced each of the following squared penalties for a given scholarship individual:

- if too much was spent on scholarship awards:
 $F_{\text{spent}} > B_{\text{spent}} \rightarrow \sigma = \sigma * \left(\frac{B_{\text{spent}}}{F_{\text{spent}}}\right)^2$
- if too much was offered in scholarship awards:
 $F_{\text{offered}} > B_{\text{offered}} \rightarrow \sigma = \sigma * \left(\frac{B_{\text{offered}}}{F_{\text{offered}}}\right)^2$
- if too many students were awarded a scholarship:
 $N_{\% \text{awarded}} > N_{\% \text{target}} \rightarrow \sigma = \sigma * \left(\frac{N_{\% \text{target}}}{N_{\% \text{awarded}}}\right)^2$
- if too few students were awarded a scholarship:
 $N_{\% \text{awarded}} < N_{\% \text{target}} \rightarrow \sigma = \sigma * \left(\frac{N_{\% \text{awarded}}}{N_{\% \text{target}}}\right)^2$

Ultimately, we multiplied the output of the fitness function (i.e. the predicted enrollment count for an individual) by the penalty coefficient to penalize constraint-violating individuals. If there were no constraints violated, the penalty coefficient was 1.0 and the fitness evaluation of the individual remained unchanged.

3.5.4 Optimization Process

The approach for the GA was as follows. We randomly generated the initial population of individuals as described

above. We then calculated the fitness of each individual and took a subset of the most fit individuals (10%) as the basis for the next generation of the population. We then employed genetic crossover to this subset of the population to generate offspring. We used two-point genetic crossover, wherein two points were randomly selected along chromosomes and the genetic material from one individual was swapped with that from another between the two points, much like a two-point crossover mutation in nature. In other words, for a pair of randomly selected individuals, we randomly selected two scholarship bins from ventiles 1 through 20 and all scholarship award values between the two bins from one individual were swapped with those from the other individual and vice versa.

After using crossover to refill the population, the offspring underwent mutation. We used three types of mutations: an increase mutation, a decrease mutation, and a swap mutation. For a mutation, we randomly selected an individual and then randomly selected a bin from this individual. The award for this bin was either increased to another possible award amount (increase mutation), decreased to another possible award amount (decrease mutation), or swapped for another randomly selected award amount (swap mutation). The probability of performing either an increase, decrease, or swap mutation were equal unless the scholarship award value equaled S_{\min} or S_{\max} , in which case we eliminated the possibility of a decrease or an increase mutation, respectively. Once a particular mutation was selected for a given individual and bin, a single award value was randomly selected from all possible award values that satisfied the condition of the mutation and used in the mutation. After mutations, we re-sorted the awards across each individual to ensure students with higher academic profiles received larger awards. We kept the initial subset of the most fit individuals unchanged during crossover and mutation; instead, we altered replicas of these individuals to compare the most fit individuals from one generation to those from the next generation. The new generation of individuals then served as the population for the next algorithmic iteration. We repeated this process for 20 generations of the population and used the most fit individual thereafter as the scholarship allocation strategy. The process for the GA is shown in Process 1.

Process 1: Genetic algorithm process for scholarship allocation (parameters for this work are in parentheses)

- 1: Initialize population ($p = 1000$ with $K = 20$ bins each)
- 2: Evaluate fitness of each individual (where fitness is enrollment count predicted by classifier)
- 3: For each of G generations: ($G = 20$)
- 4: Keep subset of population with highest fitness (10%)
- 5: Use two-point crossover to fill population
- 6: Mutate random bins of random individuals
- 7: Evaluate fitness of each individual
- 8: Use individual with highest fitness after G generations

4. RESULTS AND DISCUSSION

Using the methods described in Section 3, we developed a predictive classifier of student enrollment and used it in conjunction with a genetic algorithm that optimized the allocation of a scholarship fund. Ultimately, the university saw a

Table 1: Classifier performance sorted by rank across all metrics. Names of classifiers are provided in Section 3.4.

	Model	Accuracy	AUC	F1-score
1.	XGB	93.10%	0.846	0.905
2.	RF	93.06%	0.848	0.901
3.	MLP	93.01%	0.845	0.902
4.	BC	93.05%	0.833	0.901
5.	LR	92.96%	0.805	0.900
6.	SVM	93.00%	0.780	0.900
7.	KNN	92.80%	0.793	0.893

23.8% increase in enrollment yield after using our approach. This resulted in millions of dollars of additional annual tuition revenue. The following section presents these results in greater detail in the same order as the methods.

4.1 Predicting Enrollment

Previous studies have shown the effectiveness of ML in predicting enrollment. We examined seven different predictive classifiers for this task. We show the performance of these classifiers in terms of prediction accuracy, AUROC, and F1-score in Table 1. We used the same observations as a test set when comparing performance across classifiers; for the test set, the majority class represented 92.8% of observations (i.e. 7.2% of students in the test set eventually enrolled at the University). All classifiers performed similarly in terms of both accuracy and F1-score. Because of the large class imbalance, there were only modest gains in terms of accuracy over the majority class representation. Ensemble classifiers (RF, XGB, and BC) had the highest accuracies while KNN performed on par with the majority class representation (note: it was checked that the KNN model did not predict that all observations were of the majority class). The highest F1-score, meanwhile, was given by the XGB classifier, though it was not substantially higher than other classifiers.

We show ROC curves for the classifiers in Figure 3. The general shape of the ROC curves was similar across the classifiers but with meaningful variation in AUROC. Specifically, RF, XGB, and MLP tended to perform similarly in terms of AUROC and had the highest AUROC values. This is in line with previous work where neural networks tended to perform well when predicting enrollment, even without more complex architectures in this case. That said, the ensemble classifiers performed similarly well for the task at hand.

Demographic data was not used in the models. Including demographic variables in the prediction models would improve predictive performance to some degree, albeit at the expense of potential explicit discrimination with respect to recipient characteristics. As such, we decided to exclude demographic variables when building the classifiers. While doing so limits the degree of explicit discrimination, the possibility of implicit discrimination remains - particularly with respect to associations between demographics, income, geography, and academics. Checking and controlling potential demographic imbalances is beyond the scope of this particular

Figure 3: ROC curves for enrollment prediction

work but was handled by stewards of the DNR scholarship fund after optimization. It should again be noted that the DNR scholarships were designated to be awarded in a merit-based manner and financial need was not be considered in the allocation process.

We examined classifier performance across all metrics and decided to use XGB when optimizing scholarship allocation. Prior to optimization, we calibrated the classification threshold for the prediction probability to the nearest one-hundredth such that the number of students predicted to enroll by the model was nearest to the actual enrollment count. By calibrating the threshold in this manner, we used a lower probability decision threshold (0.22) than the value of 0.5 that is typically used in binary classification. We understood that doing so came at the expense of an increased rate of false positives (Type I error) but it also allowed for the predicted enrollment counts to be closer to actual counts, which was necessary when discussing predictions with administrative stakeholders. We show the effects of this calibration in Figure 4, where the confusion matrix using the standard classification threshold of 0.5 is shown along with the confusion matrix using the calibrated threshold of 0.22.

Of note from the confusion matrices is how well students who did not enroll at the University could be identified. On the other hand, it was much more challenging to identify those who would enroll. This speaks to the selectivity of the University in that many of the candidates who would not enroll were simply those who were not accepted to the University (students' acceptance to the University was not included as

Figure 4: Confusion matrices for predicting enrollment using XGB and a classification threshold of 0.5 (left) and a calibrated classification threshold of 0.22 (right)

Table 2: Predicted enrollments after calibrating the classification threshold for test data and all data (training + test data).

	Test Data	All Data
Actual	1,032	5,081
Predicted	1,049	5,166

a feature during predictions). Concurrently, the difficulty with identifying students who will enroll aligns with the fact that these DNR students are applying to a university that is away from their respective homes and social bases. Also, those that are accepted to the University tend to be of higher academic standing, giving them more potential college choices. Thus, the general likelihood of a DNR student enrolling is difficult to determine when considering potential social factors and college options.

Lowering the classification threshold resulted in predicted enrollment counts in line with what was seen in the data, as shown in Table 2. Calibrating the classification threshold also allowed for a greater number of true positives while also balancing the number of false positives and false negatives. We also examined the effect of similarly calibrating the classification thresholds when using the other ML classifiers and determined that using XGB would still be viable for scholarship optimization.

4.2 Optimizing Scholarships

After we developed a model for predicting student enrollment, we used a GA to design a scholarship disbursement strategy. We used the GA in a setup with students grouped in ventiles and each ventile receiving the same award amount. The genetic material (awards for each ventile) for individuals (allocation strategies) was altered for each iteration of the GA and then fitness was determined. Fitness was based on predicted enrollment after accounting for the violation of constraints. Due to the application review timeline at the University, we did not know which students of the 2018 entering class would be admitted and used the prior year’s application data (2017) to develop a disbursement strategy. Because the disbursement strategy relied on students being grouped into ventiles, we applied it to the most recent entering class after checking that the two classes were similar across academic-related variables using paired t-tests and chi-squared tests. Additionally, the binning strategy and the use of ventiles alleviated concerns about the size of the entering class as specific award amounts were disbursed to proportions of the admitted class and not to a fixed count thereof.

We show fitness (predicted student enrollment) measures across the population of individuals for each generation of the GA in Figure 5. As expected, the maximum, mean, and median values of fitness increase across generations, though these increases are much smaller for later generations. The minimum fitness values for the population follow a similar trend with some variation. All metrics eventually converge to the predicted enrollment, which is shown as a percentage. We intend to use Monte Carlo simulations in the future to outline a distribution of likely enrollment counts during the

optimization process.

The exact award amounts for the DNR scholarship cannot be disclosed due to University policy. Additionally, the percentage of students receiving scholarship awards was not consistent across previous years. For example, in some years, 30% of accepted DNR students may receive a scholarship while in other years, 70% of accepted DNR students may receive a scholarship. Furthermore, tuition charges change annually at the University. Thus, in an attempt to provide a normalized measure for comparison across entering classes without disclosing exact award amounts, we compare award allocation strategies across time based on the discount on tuition. For example, a student receiving a \$5,000 scholarship when tuition is \$20,000 receives a 25% discount on tuition. We show previous allocations of the DNR scholarship to scholarship-receiving students as a discount on tuition in Figure 6. This discount on tuition factors in tuition cost for a full-time DNR student but not additional living or educational expenses (i.e. housing, food, books, etc). To further illustrate the use of discount on tuition, when looking at Figure 6, it can be seen that approximately 15% of all scholarship-receiving students received an award that discounted their tuition by 8-12% in 2014 while in 2017, approximately 60% of students received a similar award. For each of the bands in Figure 6 (six bands per entering class), only a single scholarship award amount fitting within a given band was given to students for a single entering class. It is apparent from examining previous allocations that the manner in which the awards were historically allocated shifted greatly from year to year. As noted previously, these previous allocations were determined by a external consulting services and we could not leverage their underlying approach or insight in this work.

We also show the scholarship allocation strategy for the 2018 entering class (for which the scholarship disbursement was optimized in this project) in Figure 6. This strategy tended to favor smaller scholarships, which aligns with the optimized allocation strategy that Sarafraz et al. reported [19]. In fact, scholarship stewards had initially placed a lower limit on the scholarship awards (S_{\min}) during modeling, which was equal to the lowest scholarship amount that had historically been awarded to students. This lower limit was between a 8-12% discount on tuition. After we discussed preliminary results of the optimization and the effectiveness of smaller awards with the scholarship stewards, it was determined that the lower limit on the awards would be changed

Figure 5: Fitness measures across generations of genetic algorithm. Fitness was equivalent to predicted enrollment.

Figure 6: Historical scholarship allocations for the DNR scholarship. The highlighted year (2018) shows the optimized scholarship allocations from this work. Upper bounds for the bins indicating discounted tuition are inclusive. Percentages of students given awards are percentages of award-receiving students only.

Table 3: Historical, predicted, and actual yields after scholarship disbursement.

	Timeframe	Yield	% Increase
Historical	2014-2017	10-12%	N/A
Predicted	2018	13.9%	15.8%
Actual	2018	14.8%	23.3%

to $\frac{S_{\min}}{2}$. Thus, the 2018 entering class had some scholarship awards that were lower than those received by previous entering classes. These lower awards discounted tuition by 4-8%. It is also noteworthy that the optimized disbursement strategy gave a distribution of awards that was right-skewed (with more of the awards being lower in value), in contrast to previous allocation strategies, which were predominantly left-skewed (with more of the awards being higher in value) or near uniform. This speaks to the idea that smaller scholarships awarded to students of lower merit may be more effective than larger scholarships are for those of higher merit (keeping in mind that students who received smaller awards were also of lower merit for this merit-based scholarship). This aligns with intuition that those with higher academic profiles have more college options and require additional recruitment, be it additional financial aid or in some other form. It could also relate to the idea that higher-performing students come from more advantaged socioeconomic backgrounds, thereby diminishing the effect a scholarship may have on their enrollment decisions.

After we developed the scholarship distribution strategy for the 2018 entering class, the University distributed scholarship awards to admitted DNR freshmen. We then waited as these students indicated their enrollment decisions a few months later. In recent years, the yield for DNR students at the University was about 10-12% with little/no increase, as verified by scholarship stewards, where “yield” refers to the percentage of admitted students who enrolled at the University. Historical yields were not based on an un-optimized or randomized scholarship allocation strategy but were the product of the scholarship allocations derived by external consulting services. Thus, because we were comparing the results from our approach to those from a previously optimized strategy (and not an un-optimized or random allocation strategy), we expected to see a modest improvement,

if any at all. Instead, we saw a much higher increase in yield. Table 3 shows the historical yields, the predicted yield based on our optimized approach, and the actual yield based on student enrollment for the 2018 entering class. When comparing to the upper bound on historical yield (12%), we anticipated that the scholarship optimizations would increase student yield by 15.8% (12% to 13.9%) based on the enrollment numbers we had seen during the optimizations (which was computed using XGB and the calibrated classification threshold). In reality, yield increased by 23.3%. This amounted to hundreds of additional students enrolling with each paying tens of thousands of dollars annually in tuition. There was also no discernible difference between the academic aptitude of students from the 2018 entering class and years prior. Overall, the net effect was an increase in millions of dollars in annual tuition revenue for the University. The University has since incorporated our approach into their enrollment modeling process for future disbursements of this scholarship fund. Of note is that yields are based on proportions of students that enrolled and the size of the entering class makes little difference when comparing yields. The University also admitted roughly the same percentage of DNR students as years past and nearly all conditions during the application process were identical to previous entering classes. That said, the degree to which this increased yield can be causally attributed to the scholarship optimizations warrants further investigation. This may be in the form of A/B testing or some other controlled experiment.

5. CONCLUSIONS

In this work, we show how existing data at a university can be used to improve enrollment management. We combine machine learning with numerical optimization and use student application data at a public university to optimize a scholarship fund. We find that the optimized approach increased student enrollment and generated millions in tuition revenue. Our approach has been incorporated into the university’s enrollment forecasting.

We show that ensemble classifiers can give strong performance when predicting enrollment and we use a binning strategy based on student merit to make the optimization task more tractable. This strategy eliminated the need for per-student optimizations, thereby limiting the complexity of the fitness landscape during optimization. After optimization,

tion, we see that smaller scholarship awards work better for maximizing enrollment. In all, the University had historically seen little/no increase in enrollment yield and we projected that our optimized approach would increase yield by 15.8%. In reality, enrollment yield increased by 23.3%.

Universities are at the forefront of training the next generation of data scientists and developing data-centric tools and techniques. However, they are far behind in applying data science to their own administrative data and processes. This project attempted to move them in this direction. Using a suite of machine learning tools, we were able to increase a university's revenue from a scholarship fund by millions of dollars. We think there are many similar opportunities to harness the power of data science in the realm of education administration, especially in resource allocation.

ABSTRACT

Online courses often include discussion forums, which provide a rich source of data to better understand and improve students’ learning experiences. However, forum messages frequently contain private information that prevents researchers from analyzing these data. We present a method for discovering and redacting private information including names, nicknames, employers, hometowns, and contact information. The method utilizes set operations to restrict the list of words that might be private information, which are then confirmed as private or not private via manual annotation or machine learning. To test the method, two raters manually annotated a corpus of words from an online course’s discussion forum. We then trained an ensemble machine learning model to automate the annotation task, achieving 95.4% recall and .979 AUC (area under the receiver operating characteristic curve) on a held-out dataset obtained from the same course offered 2 years later, and 97.0% recall and .956 AUC on a held-out dataset from a different online course. This work was motivated by research questions about students’ interactions with online courses that proved unanswerable without access to anonymized forum data, which we discuss. Finally, we queried two online course instructors about their perspectives on this work, and provide their perspectives on additional potential applications.

Keywords

Text anonymization; discussion forums; online learning.

1. INTRODUCTION

Online education is an essential part of many university programs [12] and has many potential benefits, such as convenience, scalability, and lower cost for both students and institutions. However, personal connections and discussions with fellow students could be quite negatively impacted if there are no

opportunities for students to interact with each other as they can easily do in face-to-face classes. Hence, many online courses include optional or required discussion forums, in which students can talk about course content or connect with each other. For researchers, the textual contents of these forums is a valuable source of knowledge for understanding more deeply how students experience learning in online environments (see studies such as [4, 6, 8, 11, 16, 18, 23, 26, 37]). A significant barrier to analyzing the contents of these forums is the private nature of information students can and do disclose to each other, such as names, affiliations, locations, and contact information. Analyzing these data often requires anonymization before researchers can ethically and legally access the data for analyses. In this paper, we propose and evaluate a method specifically designed for anonymizing student-generated text in discussion forums.

There are various types of identifying information students share on discussion forums. Some are relatively straightforward to remove, such as phone numbers and email addresses, which follow a relatively limited set of formatting patterns. Others are less predictable – especially the names of people and places, which can appear in various forms (e.g., nicknames), overlap with dictionary words (e.g., May, Lane, Bob), or refer to entities not listed in course rosters (e.g., family members, locations). For example, one student in data we analyzed posted potentially identifying information about a pet:

“Hello [REDACTED], I am also a pet lover. I have a [REDACTED] schnauzer, whose name is [REDACTED]. What’s your work at the dog kennel? How many puppies are there in the kennel? It seems lots of fun!”

While other students refer to themselves or others by alternate names, as in the case of this student:

“Hi guys, My name is [REDACTED], but I prefer to be called [REDACTED]. I was born and grew up in [REDACTED], but I moved to [REDACTED] when I was in 7th grade.”

Moreover, students frequently misspell identifying and non-identifying information (e.g., “*Battlestar Gallactica*”, “*When we icnrease entropy does it change delta G as well?*”), which – combined with grammatical errors – resulted in relatively poor anonymization quality in our early efforts built on named entity

Nigel Bosch, Wes Crues, Najmuddin Shaik and Luc Paquette
“Hello, [REDACTED]”: Protecting Student Privacy in Analyses of Online Discussion Forums” In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 39 - 49

recognition software. Hence, we sought more robust methods to detect identifying information to be redacted.

Identifying information can occur in forums when students organize study groups, address questions and answers to each other, and other situations. Students may receive meaningful benefits from exposing private information online – for example, if it enables them to connect more closely with peers they may never meet offline. Examples such as those above are especially common in introductory discussion forums at the beginning of courses, where students get to know each other. However, the presence of identifying information prevents researchers at many academic institutions offering online courses from analyzing forum data (at least without individual permission from each student), and thus from enhancing student learning experiences through applications of research. We focus on this problem for the specific case of university-level online courses, of which there are many, and propose an automated text anonymization solution that rivals human accuracy, despite the variance in form, content, and spelling inherent in student-generated text.

1.1 Privacy Concepts and Anonymization Strategies for Text

There is a large body of previous research on removing identifying information from text. A primary focus of prior work has been specifically on removing names and identifying information from medical records (see [24] for a review). One of the earliest methods employed a template-matching approach to find names, addresses, phone numbers, and other identifying information in medical records (e.g., notes written by doctors) [35]. Later research with similar methods has shown that template-matching approaches can be quite accurate in held-out (unseen) medical records data, achieving a recall of .943 [28], which compared favorably to inter-human agreement on the same data.

Early work on anonymizing text also led to the concept of k -anonymity [33, 34], in which a formal guarantee is made for a particular dataset that every person in that dataset is indistinguishable from $k-1$ or more other people in the dataset. This has resulted in additional text anonymization research that goes beyond names of people and places to include identifying characteristics such as specific diseases and treatments that may be sufficiently unique to reduce k with some effort [3]. In general, these works utilize lists of known names and forms of names (e.g., “Dr. [name]”) to identify words for removal in text – forms which are used infrequently in online course discussion forums – and tend to focus on the unique needs of medical literature anonymization.

Named entity recognition (NER) is another closely-related field that focuses on finding *and classifying* names in text [25]. Modern NER approaches typically rely on machine learning to discover names in text by learning from large corpora of annotated or partially-annotated text. In theory, NER can be applied for anonymization purposes by finding names and removing or replacing those from classified categories of interest (i.e., people, places, and organizations that may be employers) [10]. However, modern NER systems are typically trained on large amounts of data that differs considerably from discussion forum data (e.g., the entire contents of Wikipedia), and do not generalize well to new domains [20, 21].

Previous research has also studied privacy and anonymity in structured data (e.g., directed graphs, tabular records) that is relevant to forum anonymization. For example, social network analysis shows that individuals in one social network can be

identified in another network based on who they interact with [27], which might occur across course discussion forums. The network of semantic and stylistic relationships between words can also identify individuals from text data [2, 5]. Such connections have led to the concept of differential privacy. Differential privacy is one of the strongest types of data privacy [14], which guarantees that it is impossible to determine whether or not a query individual’s data was included in a given dataset or result. While we do not propose providing such a strong guarantee for anonymizing discussion forum text for research analyses – given the need for obfuscating much of the text that could be needed for analyses (e.g., person-specific sentiment words) – we instead propose a set of goals that allow well-intentioned researchers to access data with minimal exposure to identifying information.

1.2 Novelty of the Problem

Our method for automatically anonymizing discussion forum text aims to satisfy several goals needed for practical application. Specifically, the automatic method should:

- 1) Achieve accuracy similar to human accuracy, if it is to be used as a replacement for manual annotation
- 2) Not require annotation of large amounts of domain-specific text data for development or validation
- 3) Not rely on lists of student names, which may be unavailable (as was the case in our work), may not capture the diversity in naming conventions of students from various cultures, and may not capture nicknames frequently used by students

Approaches relying on NER methods satisfy goals 1 and 3 well, but not goal 2. Conversely, approaches developed for the needs of medical record anonymization typically satisfy goal 1 and potentially goal 2 (though this has not been well tested and may not be the case if the style of medical text differs notably from online discussion forum text), but typically do require information such as lists of individual’s names, and do not satisfy goal 3.

The approach we propose here satisfies the three goals outlined above, utilizing a set-theoretic approach to drastically reduce the burden of manual annotation and machine learning to further automate the manual annotation process.

2. ANONYMIZATION METHOD

The anonymization procedure consists of three broad steps (see Figure 1 for an overview). First, we extract a set of possible name words from the discussion forum text. Second, we classify possible names as either actual names or not names, via manual annotation or machine learning. Third, we remove the identified names from text, along with other likely identifying information that can be found via regular expressions, including emails, URLs, and phone numbers.

2.1 Data Collection

We obtained discussion forum text data from two online courses offered at a large, public university in the Midwestern United States. The first course (*course 1*) was an elective STEM course offered using the Moodle learning management system [13], while the second course (*course 2*) was an introductory STEM course that was required for students in some majors and was offered using the LON-CAPA learning management system [22]. Discussion forum participation was a required, graded component of both courses, and students were quite active in the forums. We obtained two semesters of course 1 data separated by two years and one semester

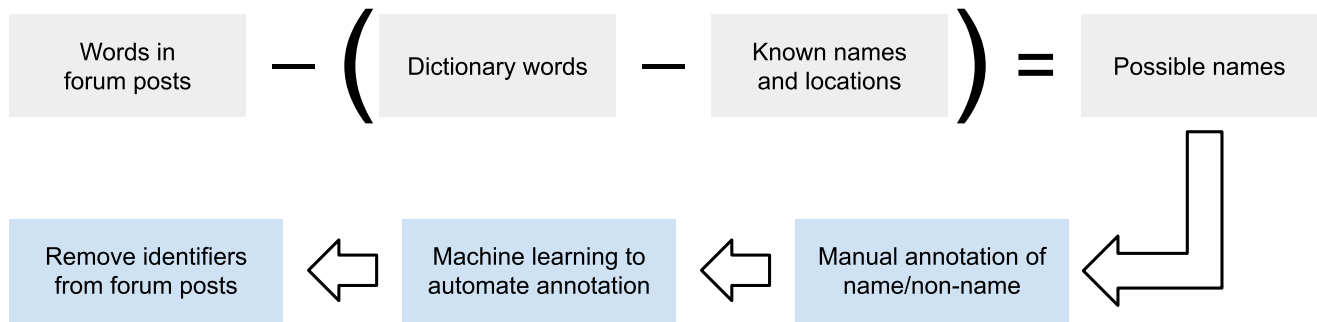

Figure 1. Anonymization method overview. Grey boxes indicate data, blue boxes indicate processing steps. Minus signs indicate set subtraction.

of data for course 2. In the first semester of course 1 there were 14,082 posts made by 226 individuals – including the instructor, whose identity and forum posts also need to be anonymized. In the second semester of course 1 there were 9,217 posts made by 295 individuals, and in course 2 there were 930 posts made by 78 individuals. Forum activities consisted of personal introductions, questions about and discussions of topics in the course, team formation/coordination for group projects, and others.

We developed the anonymization method by examining the largest dataset (the first semester of course 1, referred to as *training data*) and utilized the remaining two datasets as completely unseen held-out testing data. The second semester of course 1 (referred to as *holdout 1*) provides a test of generalization of the method over time, while course 2 (referred to as *holdout 2*) serves as a test with a different course topic, learning management system, and instructor.

We obtained approval from our institutional review board and the instructors of the courses before collecting and analyzing data. However, we were only permitted to access anonymized data for analyses. Hence, we developed the anonymization method in cooperation with university data warehouse staff, who ran code for analyses on original forum data and shared the anonymized results.

2.2 Narrowing the List of Possible Names

There are several possible categories for each word (sequence of consecutive non-whitespace characters, after removing punctuation) in a discussion forum post. The word may be an identifying name referring to a person or a place, an English word¹, a misspelling, or a non-English word (e.g., numbers, other languages). The most challenging and time-consuming aspect of anonymization is to determine whether a particular word is identifying or not. We applied a set-theoretic approach to drastically reduce the scope of the problem, narrowing down the list of all words in forum posts to a small subset of possible names, which are then much less time-consuming to annotate.

The top row of Figure 1 illustrates the possible name extraction process. We started with a dictionary of over 100,000 English words [36], including common loanwords, and removed any words that overlapped with a list of over 23,000 cities, political regions, and countries (words such as South, New, etc. that were part of place names)². We then also removed any words from the

dictionary that overlapped with a list of over 7,000 first and last names obtained from U.S. census data. Thus, the dictionary contained only words that were not the names of people or places – words like *wormhole* and *dalliance*, but not *so* or *will*. We then removed these non-name dictionary words from the list of all unique words in discussion forum posts, leaving only possible names.

2.3 Feature Extraction

We extracted various features to help both human annotators and machine learning models classify each possible name as a name or non-name word. Features can be categorized into two basic types: densely-distributed *ad hoc* features and sparsely-distributed word presence features. Ad hoc features calculated for each possible name consisted of:

- Count of occurrences
- Word index in the first post where the word was used
- Count of words in the first post where the word was used
- Proportion of occurrences where the word was capitalized
- Proportion of occurrences where the word was at the beginning of a sentence
- Proportion of mid-sentence occurrences (not at the beginning of a sentence) where the word was capitalized
- Proportion of occurrences where the word was mid-sentence and capitalized
- Whether the word was a dictionary word or not (before modifying the dictionary)
- Whether the word was in the U.S. census list of first/middle names
- Whether the word was in the U.S. census list of last (family) names
- Frequency of the word in the U.S. census list of first/middle names

¹ This paper focuses on English-language text. However, the method could be repeated for other languages by replacing English-specific components (e.g., the dictionary) with another language.

² Obtained from <http://www.geonames.org>

- Frequency of the word in the U.S. census list of last names
- Whether the word was in the list of world cities
- Whether the word was in the list of political regions (e.g., states, territories)
- Whether the word was in the list of countries
- Count of dictionary words that were within one edit (deletion, insertion, replacement, or transposition) of the word
- Count of dictionary words that were within two edits of the word

The list of ad hoc features resulted from several rounds of error analysis and iterative refinement, which was necessary to reach classification accuracies comparable to human raters. Feature development proceeded approximately in order of complexity. Our original features consisted of the simplest ideas such as the count of occurrences. Complex features, such as the proportion of capitalized mid-sentence occurrences, resulted from examining prediction errors from models with simpler features. While this process may have resulted in over-fitting the feature extraction process to training data, we made no adjustments to features for final evaluation on the holdout datasets (see description of dataset annotation below).

Word presence features indicated the presence or absence of a particular word within the 10 most common words preceding the possible name word, which we refer to as context words, among all of its occurrences across forum posts. We tracked the most common context words separately for capitalized mid-sentence occurrences, capitalized occurrences, and all occurrences. This separation helps to determine whether common dictionary words like “hope” were also names. Word presence features consisted of a 1 if a particular word appeared in the ten most common context words for the possible name in question, and a 0 otherwise. Word presence features captured things like if a word was preceded by “hi” or “hello” – words which tended to indicate the presence of a name. We limited these features to the 25 most common overall context words, yielding 75 total context word presence features (since there were 3 capitalization conditions). Additionally, we included an “other” count category for all less-common context words, yielding another three features (one for each capitalization condition). For example, the words “tea” and “coffee” might occur among the 10 context words for a particular possible name, but be too infrequent across all possible names to rank in the top 25; we would thus count these both as “other” and calculate features for the number of “other” words in the context words for that particular name, the number of capitalized “other” words, and the number of “other” words capitalized in the middle of a sentence. Thus there were 95 features in total: 17 densely-distributed and 78 sparsely-distributed.

2.4 Manual Annotation of Possible Names

Two raters iteratively annotated possible names derived from the training data, checked agreement, and updated an annotation scheme to resolve patterns of common disagreement. Annotators had access to features listed above, as well as the possible names themselves. They did not, however, have access to the actual forum posts nor to associated possible name pairs (first and last names together), thereby mitigating unnecessary exposure to possible identifying information.

In the first round, raters annotated 200 randomly-selected possible names as either names, non-names, or unknown. Of these 200, they annotated 10 as unknown. The annotation guide was subsequently revised to remove the unknown category, since ultimately a name/non-name decision must be made for anonymization, and to clarify unknown cases. Unknowns primarily consisted of famous individuals’ names (e.g., Obama), which we classified as names out of an abundance of caution. For the remaining 190 cases, the raters achieved 87.4% agreement and Cohen’s $\kappa = .734$ (confidence interval = [.634, .833]).

Raters annotated a different set of 200 randomly-selected possible names in the second round to test the updated annotation guide. They achieved 89.5% agreement and $\kappa = .773$ (confidence interval = [.681, .865]). After this round we added the mid-sentence capitalization features described above, to help disambiguate disagreements noted by the raters.

Raters completed a third round of annotation to test the final annotation guide, achieving 92.7% agreement and $\kappa = .842$ (confidence interval = [.820, .864]) on all 2,588 instances in the training data, indicating excellent agreement [7]. After this round they also annotated a sample of 650 randomly-selected possible names from the holdout 1 dataset, though we removed 50 of these when we later discovered that they were erroneously included due to UTF-8 encoding issues. This left a holdout sample of 600 possible names, which we deemed sufficient to produce a tight confidence interval for agreement, given the confidence intervals previously obtained with just 200 possible names. On the holdout 1 dataset the raters achieved 93.8% agreement, with $\kappa = .864$ (confidence interval = [.823, .907]), indicating that they were able to apply the annotation guide to a new dataset with at least as much agreement as the original dataset. Finally, raters discussed each of their disagreements to reach a definitive name/non-name label for each of the 600 possible name instances in holdout 1.

A single rater annotated a sample of 600 possible names in the holdout 2 dataset as well. Given the excellent agreement between raters, we deemed a single rater sufficient for this task. Specifically, the more conservative rater (higher recall; see rater comparison in Table 1 results) annotated the holdout 2 dataset.

The final data thus consisted of 2,588 labeled instances in the training dataset (35.5% annotated as names), 600 in holdout 1 (36.0% annotated as names), and 600 in holdout 2 (44.5% annotated as names), which we used to train and validate the automatic name classification procedure.

2.5 Name/Non-name Classification

The process of extracting possible names greatly reduces the burden of manual annotation and limits raters’ exposure to identifying information. We sought to further reduce these concerns by automating the classification step.

We evaluated two quite different machine learning approaches and ultimately combined them via decision-level fusion. The first classification algorithm was *Extra-Trees* [15], which is a variant of Random Forest that trains multiple trees (500 in our case) based on random subsets of data, and adds further randomness by choosing random points at which to divide the data in feature space. Extra-Trees makes no strict assumptions about data distribution, and thus works well for the features in this paper, which include densely- and sparsely-distributed features with vastly different ranges and distributions. Moreover, Extra-Trees has inherent feature selection (dimensionality reduction) capabilities, since irrelevant features can simply be ignored when constructing each tree. We utilized the

implementation of Extra-Trees available in *scikit-learn* for this model [30].

The second approach we evaluated was a deep neural network (DNN) implemented with *TensorFlow* using the stochastic gradient descent optimizer [1]. We developed a custom structure for the DNN to suit the specific properties of the problem (Figure 2). The feature space is relatively large (95 dimensions) for a model with no inherent dimensionality reduction capabilities, so we added regularization to constrain model complexity. The densely- and sparsely-distributed features call for different regularization methods, however. Several of the densely-distributed features were highly correlated, and the number of features (17) was relatively small. Thus, we applied L2 regularization for densely-distributed features [29]. Conversely, we applied L1 regularization to the sparsely-distributed features, of which there were many (78), since L1 pushes the weight of irrelevant features toward 0. We then concatenated the post-regularization outputs of fully-connected layers for densely- and sparsely-distributed features, and stacked additional fully-connected layers (which were regularized via dropout [31]). Finally, we added a fully-connected sigmoid activation output layer (i.e., logistic regression) to predict name or non-name.

We evaluated models via nested four-fold cross-validation on the training dataset. In this approach, we randomly selected 75% of instances (possible names), trained a model on those instances, and tested it on the remaining 25% of instances. We repeated the process three more times so that each instance was in the testing set exactly once. During training, we weighted false negative errors (incorrectly classifying a name as a non-name) twice as heavily as false positive errors (incorrectly classifying a non-name as a name), since we were more concerned about missing identifying information than about accidentally removing non-identifying words. False positive errors might adversely affect some analyses (e.g., if the word “joy” was mistaken for a name, thereby changing the result of sentiment analysis), but would not harm student privacy.

We tuned hyperparameters (model settings) for both models via nested cross-validation, in which we tested different hyperparameters and selected the best combination of hyperparameters based on cross-validated mean squared error. Note that this step took place nested within training data only, via 4-fold cross-validation within the training data of the outer 4-fold cross-validation loop, so that hyperparameters were not selected based on test set accuracy.

For the Extra-Trees model, we tested hyperparameters consisting of the minimum number of instances required for each leaf of the tree (values of 1, 2, 4, 8, 16, or 32) and the maximum proportion of features to consider when creating each tree branch (values of .25, .5, .75, or 1.0). For the DNN, we searched hyperparameters including the number of neurons in each hidden layer (2, 4, 8, 16, or 32), L2 regularization strength (.1, .01, or .001), L1 regularization strength (.1, .01, or .001), dropout regularization strength (0, .25, or .5), number of hidden layers after the concatenation layer (0, 1, 2, or 4), and the learning rate (.01, .001, or .0001). The hyperparameter search space consisted of the cross product of these values (i.e., grid search). Hence, training was time-consuming (several days), but the trained models can be applied to an entire course’s data in less than 10 seconds.

Finally, we re-trained the models on all training data and applied to the held-out dataset. We then combined model predictions to form a decision-level fusion model by simply averaging Extra-Trees and

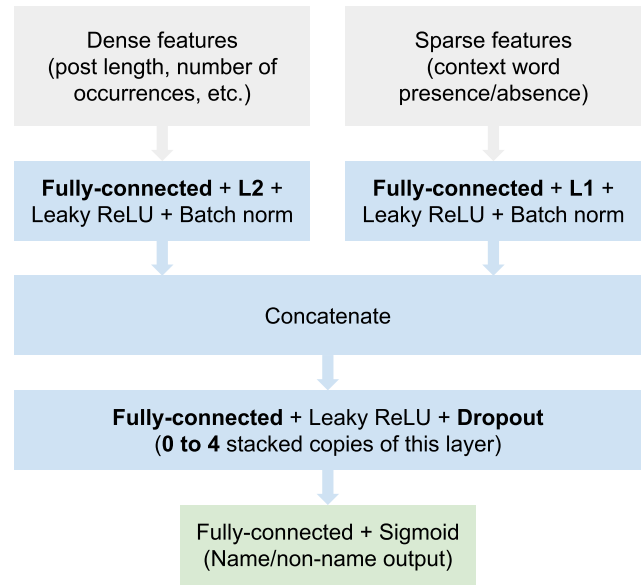

Figure 2. Custom DNN structure. Elements marked in bold were hyperparameters (number of neurons, regularization strength, or number of layers) tuned via nested cross-validation.

DNN predictions, for both cross-validated training set predictions and holdout predictions.

2.6 Removal of Identifiers

After names have been identified via manual annotation or automatic classification, removal of identifying information is relatively straightforward. First, we removed potential identifying information that follows known regular expression patterns, consisting of email addresses, URLs, phone numbers, and other numbers – which we removed in case they might represent things like social security numbers or other identifiers. As noted in previous research [35], such information can be identified with essentially 100% accuracy via pattern matching, and the challenging cases are names, nicknames, misspellings, and other name variants that we focus on in this paper. We replaced each pattern match with a placeholder (e.g., *phone_placeholder*) so that they could potentially serve as context words for name classification or be measured during analyses of forum content. Second, we replaced all identified name words with a placeholder, regardless of capitalization (see Error Analysis sections below for measures of how much this may result in non-name words being accidentally removed).

3. CLASSIFICATION RESULTS

We evaluated machine learning results in terms of common accuracy metrics below, but also compared human raters to evaluate the utility of the automatic approach as a replacement for manual annotation.

3.1 Machine Learning Accuracy

Table 2 contains key results of the automatic name classification method. Overall, results show that the models were highly accurate, reaching area under the receiver operating characteristic curve (AUC) as high as .981 in cross-validated evaluation on the training data, .979 on the holdout 1 dataset, and .956 on the holdout 2 dataset. AUC ranges from 0 to 1, where 1 indicates perfect classification

Table 2. Name vs. non-name classification results. FN indicates false negatives (names classified as non-names) and FP indicates false positives (non-names classified as names). Precision and recall refer to the positive (name) class. Acc refers to the percentage correctly classified.

Model	FN	FP	AUC	Acc	Cohen's κ	Precision	Recall	Base rate	N
<i>Cross-validated training data</i>									
Extra-Trees	52	202	.971	90.2%	.793	.811	.943	.355	2588
Custom NN	37	157	.981	92.5%	.841	.849	.960	.355	2588
Fusion	37	173	.980	91.9%	.828	.836	.960	.355	2588
<i>Holdout course 1 (later semester)</i>									
Extra-Trees	10	56	.976	89.0%	.772	.786	.954	.360	600
Custom DNN	11	55	.975	89.0%	.771	.788	.949	.360	600
Fusion	10	54	.979	89.3%	.778	.792	.954	.360	600
<i>Holdout course 2 (different course)</i>									
Extra-Trees	11	54	.950	89.2%	.784	.826	.959	.445	600
Custom DNN	16	61	.950	87.2%	.744	.805	.940	.445	600
Fusion	8	54	.956	89.7%	.794	.827	.970	.445	600

accuracy, 0 indicates completely incorrect classification, and .5 indicates random chance level. Thus, these results indicate models were accurate and generalized well from training data to the holdout data from 2 years later as well as the holdout data from another course.

We evaluated models with several different classification metrics in an effort to uncover any particular ways in which the method might be failing, but our primary concern was the number of false negatives – that is, the number of names misclassified as non-names. The decision-level fusion model yielded the lowest number of false negatives in each dataset (37, 10, and 8 for training, holdout 1, and holdout 2 respectively), and thus we intend to apply this model for practical use, though both of the individual models exhibited high accuracy as well.

The machine learning results also compare favorably to examples of previous work on anonymization of medical literature. In one study [28], researchers reported .967 recall on a training dataset (versus .960 for our decision-level fusion model) and .941 recall in a holdout testing set (versus recalls of .954 and .970 for our fusion model across the two holdout datasets). Moreover, our method did not require a dataset-specific list of names, as is common in previous work. While results are not exactly comparable, since base rates and predicted rates may have differed, they are strongly indicative of similar accuracy.

3.2 Comparison to Human Raters

Measuring annotation agreement between two human raters is one way to determine how “difficult” a task is, and whether a machine learning solution is close in accuracy. We computed machine learning model accuracy by comparing predictions to the resolved set of labels produced by raters; here we compare raters (pre-resolution) to each other. Since neither rater necessarily represents the ground truth more than the other, we computed comparison metrics alternately treating each rater as the ground truth.

Table 1 shows these results computed with the same accuracy metrics as the machine learning model, using the holdout 1 dataset.

Results show that the machine learning method was close to, and in some respects equally as accurate as the human raters. Recall and false negatives (FN) are especially important to consider for minimizing the risk of identifying information being revealed, and both showed that the fusion machine learning model (recall = .954, FN = 10) was close to or better than human accuracy depending on

Table 1. Details of human raters' agreement, treating each rater as ground truth individually to allow comparison to machine learning accuracy on the same task. AUC refers to the minimum proper AUC (calculated via linear interpolation with a single point) because raters provided only yes/no annotations, not probabilities.

	Ground truth	
	Rater 1	Rater 2
FN	30	7
FP	7	30
AUC	.945	.923
Acc (% agreed)	93.8%	93.8%
Cohen's κ	.864	.864
Precision	.864	.964
Recall	.964	.864
Base rate	.360	.360
N	600	600

which rater we considered as ground truth (recall .864 or .964, FN = 30 or 7). Note, though, that for cases where algorithmic recall exceeds human rater recall, human rater precision is correspondingly better since it is reciprocal with recall when treating a single rater as ground truth. In terms of κ , human raters do seem likely to be superior to the machine learning fusion model ($\kappa = .864$ versus .778). Thus, for some sensitive applications of the method, human raters may be needed. However, the fusion model primarily makes false positive (FP) errors, which are less of a privacy concern than FN errors.

The difference in FN between raters (FN = 7 versus 30) also indicates that there was some inconsistency in terms of tendency of one rater versus the other to make a classification of name or non-name. This is one potential advantage of making continuous-valued predictions (probabilities, in this machine learning case) of name versus non-name, because it allows setting a threshold. For human raters, thresholds are implicit but not easily or specifically controllable. As noted previously, we weighted false negative errors twice as heavily as false positive errors, though that is a parameter that could be adjusted for the particular needs of a dataset.

4. HOLDOUT 1 (LATER SEMESTER) ERROR ANALYSIS

We conducted an analysis of cases where machine learning predictions were incorrect, focusing on the decision-level fusion model applied to the holdout 1 dataset. Analysis of false negatives is important to discover the severity of cases where names are left unredacted, while analysis of false positives is important to quantify the amount of text that will be unnecessarily anonymized (replaced with placeholders).

4.1 False Negatives

False negatives are the most serious errors, since they may result in identifying information being revealed. There were 10 false negatives, which we examined to determine how serious these errors might be and to determine why they might have occurred. Human raters disagreed on 6 of the 10 words (and they only disagreed 37 times total – see Table 1), and only agreed to classify those 6 as names after discussing. This indicates that these were exceptionally difficult cases, even for humans. Furthermore, the machine learning method made similar false negative errors as human raters.

Of the 10 false negatives, there were 2 dictionary words (“long” and “mercy”), which may have indeed not been names. One of the 10 was the name of an entertainment company, which may have been an identifying characteristic (an employer) or, more likely, simply a reference to entertainment. Similarly, one was a name from a famous television show, and one was the name of a U.S. national park. The remaining words included a concatenated combination of words that was likely a filename but could have been a username, two non-English words, one name that seems likely to be a person’s first name (though it appeared only once in a forum post and was not capitalized), and one possible last name.

In sum, while there were several false negative predictions, examination of these cases reveals that even human raters initially disagreed for most of them and that it is quite possible that most of them, except probably the apparent last name, are indeed not names.

4.2 False Positives

While false positive errors are less serious, since they do not compromise identity, they do pose a challenge to subsequent analysis of forum text if important words are removed (e.g., words that might indicate sentiment, like “joy”).

The decision-level fusion model made 54 false positive errors. We observed several broad categories that capture most of these instances. First, we observed several geographical regions (e.g., “Africa”, “European”) that were too broad for our definition of identifying information – which was restricted to political regions – or even extraterrestrial (e.g., “Ganyemede”). Second, there were misspellings (e.g., “hellium” instead of “helium”), most of which were correctly identified as non-names but a few of which were not. Third, there were abbreviations such as “NBA” and “DOI”. Fourth, there were references to popular culture, such as “Overwatch” and “Kerbal”, which are indeed names but not identifying information. Finally, there were several domain-specific words, which we do not include as examples to avoid unintentional identification of the course from which data were collected.

Among these false positives, the most commonly-occurring word occurred just 26 times in 9,217 posts (the total size of the dataset from which holdout 1 data were sampled), most occurred only once, and all false positives combined appeared 191 times in those posts. This indicates that even though some non-name words were mistakenly removed from posts, the impact on the overall text was minimal.

5. HOLDOUT 2 (NEW COURSE) ERROR ANALYSIS

We performed similar analyses of classification errors for the holdout 2 dataset. However, it was not possible to compute inter-rater disagreement for the misclassified cases in holdout 2 because only one rater performed annotations.

5.1 False Negatives

There were just 8 FN errors among the 600 possible names in the holdout 2 dataset. Of these eight, three were abbreviations for university-specific terms, including a building name, a college (collection of university departments) name, and the name of a major. A further three FN errors were slang terms for large metropolitan areas with populations over 4 million. One was half of a misspelled two-word city name, and the last was a local street name.

None of the FN errors in this dataset were student names. The most serious errors are perhaps the university-specific terms, which could narrow down the identity of students when combined with other factors. However, in isolation (or even combined with each other) these terms match hundreds or thousands of students, and thus do not pose a likely risk for researchers hoping to analyze forum data.

5.2 False Positives

There were 54 FP errors in the holdout 2 dataset, which differ somewhat from the FP errors observed in holdout 1. Course 2, from which holdout 2 data were collected, utilized Roman numerals for assignment numbers, which were frequently mistaken for names. Additionally, the domain-specific content of course 2 required students to discuss a large number of letter combinations (strings) that do not represent words, and which were also often mistaken for names.

Like holdout 1, there were several misspellings mistaken for names in holdout 2 results. For example, “callender” (calendar), “hewlp” (help), and “ssolid” (solid) were FP errors. However, these account for very few redactions since these misspellings occurred only infrequently. The most notable FP was the word “my”, which occurred 293 times in the 930 posts in the holdout 2 dataset. Surprisingly, “My” was capitalized in 32.1% of its occurrences, including 15.4% of occurrences in the middle of sentences. This was somewhat unexpected, but appears to have frequently occurred when students did not punctuate the end of sentences and instead used line breaks (which we did not consider as end-of-sentence markers) to separate sentences.

Human intervention after the automatic classification step can easily correct false positive errors such as “my”, however. To facilitate this, our anonymization software produces a list of names identified by the machine learning fusion model as an intermediate step before the names are removed. The list includes the fusion model’s probability as well as the number of occurrences of each word in the original discussion forum data, sorted in descending order by occurrences. Researchers (or authorized staff in charge of anonymizing data) can thus easily examine the top of the list and delete any rows that are clearly high-impact FP errors before proceeding to the last step where names are redacted.

6. APPLICATIONS FOR INSTRUCTORS

Our primary motivation for developing this method was to enable research on the text of computer-mediated discussions students have with each other during their online learning experiences. However, such research may support the needs of course instructors as well, either directly via analysis methods they can easily apply, or via generalizable insights that can be applied to their courses. We thus sought out instructors of online university courses (who were not involved in the forum anonymization work or the courses analyzed in this paper) to gain better insight into instructor perspectives on scalable analysis of online course discussion forums. Specifically, we asked two instructors “*as an online course instructor, can you imagine any analyses of discussion forum text that would be informative for you?*”

6.1 Instructor 1

The first instructor was a male computer science faculty member with 14 years of university-level teaching experience, who had taught for-credit online courses at the university level as well as massive open online courses (MOOCs). He noted:

Specifically for all courses that I don't teach I don't have a legitimate need to know that student X is enrolled in course Y. Anonymization gives us a way to easily share forum discussions between different instructors of the same course, or across department etc. And there are numerous reasons why this is useful.

- * Potential for early detection of struggling students and the underlying cause. (Lack of time? interest? pre-reqs? effective strategies?)
- * Identification of hardest components of a course.
- * Research projects that look at common forum post across multiple courses. e.g. fresh/ sophomores/ seniors.

He also noted that when working with students to improve courses it is necessary to have anonymized data:

If I want to give the data to an undergrad staff for analysis for course improvement purposes (rather than for research publication), I'd require that they had anonymized data.

Additionally, instructor 1 conducts and publishes research on his own courses, and offered research questions and ideas he would like to pursue that would require anonymization. These included:

It may be possible to detect themes and generate hypotheses by skim reading the posts, but it is much harder to identify trends and quantitative trends (e.g. are there more X in the later part of the course). Also a general skimread of the forums will miss correlations with other data (e.g. students with background X tend to post more Y)

Can we identify when a course pace is too fast? Compared to assuming too much prior knowledge?

Suppose we consider a student's forum post action as an active intervention created by the student to affect on their own learning trajectory. How effective are these interventions? Do they also help similarly students that just read the discussion thread (and never need to post a similar issue themselves). Are they too late? Are they too early?

In sum, instructor 1 was enthusiastic about the prospect of being able to quickly anonymize online course discussion forums, and proposed several ways in which anonymization would benefit both teaching and research.

6.2 Instructor 2

The second instructor was a female statistics instructor and graduate student, with six years of university-level teaching experience. Her online courses are large, and thus provide unique challenges for teacher–student engagement. As she noted:

This semester there are about 1,400 students enrolled in [course information redacted]. It would be beneficial for me as an instructor to have some sort of automated analysis that told me which forums and topics were getting the most activity. That would help me know which forums to look at or have my undergrad course assistants look at and answer some of the questions. It would also be beneficial because if there was a lot of confusion about a certain topic, I would know I need to re-explain that topic in lecture.

I think something that identified negative words would be helpful too for the same reasons. If there's a lot of negativity on a thread- it's probably best that I go over that concept again in class to clarify any confusion.

While some of the needs noted by instructor 2 do not require access to the forum text itself (such as tools to measure forum activity), others would require researchers and developers to have access to anonymized forum text. For example, developing and validating methods for automatic assessment of confusion in forums is only possible with access to text data. Moreover, these needs highlight the difficulty of effectively utilizing online discussion forums with very large numbers of students, and the potential for automated tools to assist instructors in these courses.

7. DISCUSSION

In this study we were interested in enabling analysis of online discussion forums in university courses through removal of identifying information, even in cases where capitalization, grammar, and spelling may be unpredictable. Our results showed

that automatic anonymization is possible, and that it rivals human accuracy.

In this section we discuss implications of the results for various stakeholders, including users of the anonymization method (e.g., researchers, teachers) and students whose data is subject to analyses.

7.1 Implications for Users of the Anonymization Method

The proposed anonymization method offers two main advantages to users. First, it drastically reduces workload relative to approaches like manual identification and removal of identifying information directly from the forum text. Moreover, such manual anonymization is often intractable for users because they cannot access non-anonymized data in the first place. Second, it reduces users' exposure to identifying information. Users may either utilize the machine learning approach to avoid all involvement with identifying information, or annotate possible names manually – in which case they are still protected from seeing identifiers in the full context of the original text.

Anonymization is essential in many cases for researchers to either validate existing methods or develop new methods. For example, when automatically detecting sentiment from text with tools such as *SEANCE* (Sentiment Analysis and Social Cognition Engine; [9]) it is helpful to match sentiment to forum posts to obtain examples of the context in which sentimental language occurs. It is especially important to preserve student privacy in research that requires detailed reading of forum posts. For example, domain experts might annotate and evaluate the depth of questions students ask, or the responses they receive, to answer research questions about the relationship between a student's engagement with their peers and their status as a member of demographic groups that are traditionally-underrepresented in postsecondary education.

Finally, one important consideration for applications is how well the machine learning model is likely to generalize. We showed excellent generalization across time (2 years), as well as to a new course topic, instructor, and learning management system. While the change in topic (and instructor-specific course setup) did result in different types of errors, overall accuracy remained similar. However, we did not test across university populations. Students at other universities may have different backgrounds that influence how they interact with each other or with technology, and the vernacular language they use. Moreover, the same method could be applied to anonymize student-generated text in other contexts, such as college admissions essays [32], where students may reveal identifying information but in different (non-conversational) circumstances. Thus, for generalization to a notably different context, such as a different university or type of text, we recommend annotating a testing set of possible names to validate accuracy.

7.2 Implications for Students

The objective of our method is to minimize the potential for negative impacts on student privacy introduced by analyses of unstructured student-generated text. It is important, however, to recognize that such analyses carry inherent risk even with a (hypothetical) perfectly-accurate anonymization method. For example, students might mention their involvement in a particular

course in venues such as Twitter, Reddit, Facebook or others [39]. They may even post similar questions on course forums and public forums, or relate events that took place on course forums. It is unreasonable to expect perfect anonymization. Thus, it is important to take appropriate steps to limit public exposure to student data – even anonymized data – and to ensure that students reap benefits of analyses conducted on their data.

Positive impacts for students largely consist of 1) improvements made to future courses, and 2) additional capabilities afforded to instructors, both informed by research made possible through access to anonymized data. For example, researchers may be able to provide guidance to students about how to ask questions to elicit the most helpful responses. Or, as instructor 2 noted above, it might be possible to direct the attention of teaching assistants to students or topics where it is most needed.

Benefits to students are indirect in nature, and, in the case of research-informed changes to online courses, benefits might be more for future students than for the students from whom data were collected. Thus, more research is needed to sample student perspectives regarding analysis of their forum data, as well as their perspectives on the importance and impact of anonymization.

8. CONCLUSION

Access to discussion forum data is essential for researchers to better understand the experiences of students interacting with each other in web-based learning environments. However, access to these forum data is often hampered by important privacy concerns. Our approach for automatic anonymization of these data helps to resolve this issue, and has already enabled in-depth examination of forum posts [17–19, 38]. We plan to make our anonymization software publicly available³, and hope that it will be instrumental in advancing researchers' and teachers' knowledge of student experiences, and, ultimately improving learning in online classrooms.

m.bulathwela@ucl.ac.uk

ABSTRACT

The explosion of Open Educational Resources (OERs) in the recent years creates the demand for scalable, automatic approaches to process and evaluate OERs, with the end goal of identifying and recommending the most suitable educational materials for learners. We focus on building models to find the characteristics and features involved in context-agnostic engagement (i.e. population-based), a seldom researched topic compared to other contextualised and personalised approaches that focus more on individual learner engagement. Learner engagement, is arguably a more reliable measure than popularity/number of views, is more abundant than user ratings and has also been shown to be a crucial component in achieving learning outcomes. In this work, we explore the idea of building a predictive model for population-based engagement in education. We introduce a novel, large dataset of video lectures for predicting context-agnostic engagement and propose both cross-modal and modality specific feature sets to achieve this task. We further test different strategies for quantifying learner engagement signals. We demonstrate the use of our approach in the case of data scarcity. Additionally, we perform a sensitivity analysis of the best performing model, which shows promising performance and can be easily integrated into an educational recommender system for OERs.

1. INTRODUCTION

With the recent popularity of online learning platforms, the creation of Open Educational Resources (OERs) is increasing rapidly [16]. This recent large-scale creation of educational material demands for ways to automatically manage educational resources. In the context of OERs, this means finding and recommending material that fits the learners' goals while maximising learning outcomes. Such a goal usually entails a large personalisation factor. We define it as *contextualised engagement*, which captures how engaging a learning resource is with regard to the context of the learner (e.g., learning needs/goals and learner state). Although contextualised engagement has gained interest in the recent years [8], we argue that there is also a *context-agnostic engagement* factor, that only relates to features of the learning resource and attempts to capture the gold-standard label of population-based engagement (i.e. the marginal of contextual engagement for a resource across the population of learners). Modelling context-agnostic engagement enables identifying highly engaging resources across a population of learners before personalising educational recommendations to individuals. This paper studies the features involved in context-agnostic engagement, as a first step towards building an integrative educative recommendation system, that will join both contextualised and context-agnostic features [9].

A high quality learning resource needs to satisfy three main properties: i) academic soundness and appropriate coverage of the body of knowledge, ii) pedagogical robustness and iii) enabling learners to achieve their desired learning outcomes [24]. Learner engagement has been shown to be a proxy for (iii), as engaging with material is a prerequisite for learning. There is evidence from both online [33, 23] and classroom [30, 36] educational settings showing that higher learner engagement increases the likelihood of better learning outcomes. We thus focus on finding the general characteristics of engaging material. Using features that can be extracted across multiple modalities (video, text, audio etc.) allows developing prediction models for gold-standard engagement that are easily adaptable to a wide range of OERs and can be automated [27].

Our work is one of the first to address educational engagement prediction with video lectures, specially from a quantitative perspective. One of our primary goals is to understand if easily automatable cross-modal features can be used as predictors for how engaging an educational resource is, as

opposed to modality specific features. Although large-scale studies (involving millions of videos) have been conducted to analyse the prediction of engagement for general purpose videos [40], the largest study in the context of educational video lectures involves 800 videos from 4 courses and analyses engagement from a qualitative perspective [17]. To the best of our knowledge, this work is the first attempt to predict engagement with educational videos automatically. Our experiments involve more than 4000 video lectures that span over 20 diverse subjects, making it the largest dataset to date in this field. Our dataset, code and best performing model are released with the paper.

Given the usefulness of *predicting context-agnostic engagement* and the scarcity of work in this topic, we are motivated to answer the following research questions, which will enable the deployment of such a model in an educational platform:

- RQ1 How to encode context-agnostic engagement?
- RQ2 How effective are cross-modal language-based features for predicting engagement with video lectures?
- RQ3 Does including modality-specific features lead to a significant improvement in performance?
- RQ4 What features influence context-agnostic engagement?
- RQ5 Is predicting marginal population-based engagement useful over personalised engagement?
- RQ6 Can we assume a common underlying model for predicting engagement across different knowledge areas?

2. RELATED WORK

The interest in identifying useful and engaging information goes beyond the educational domain and is investigated in numerous other fields [10]. For example, Wikipedia uses a review system to evaluate the quality of its articles. To do so, different machine learning models, such as support vector regression and ensemble methods, are used with features such as text style, readability, structure, network, recency and review information [14, 39]. Moreover, in the context of automatic essay scoring, promising results have been obtained through rank preference support vector machines [41] and more sophisticated deep learning models [37].

Quality-based document ranking [3] and spam web-page detection [28] are other areas in the information retrieval domain that also utilises textual features and recency related features. These features categorise into different verticals such as understandability, topic coverage, presentation, freshness and authority [10].

OERs available to the public come in large-scale and various modalities [27, 19], which makes modality-specific models of limited use. As existing work proposes models with domain/modality specific features (e.g. network features of Wikipedia [15] or speaker speed in videos [17]), there is a need for models that can evaluate how engaging educational materials are at scale using a cross-modal feature set. We attempt to address this gap through this work.

2.1 Why Modelling Engagement?

As argued by Lane [24], a well designed learning resource should enable the learner to achieve the expected learning outcomes. Prior work has studied *learner engagement* in Massively Open Online Courses and shown that when optimised, **engagement can increase the likelihood of achieving better learning outcomes** [33, 23]. User engagement has also been shown to differ greatly from popularity measures such as number of views [40], as the latter does not necessarily capture whether learners consume the material. In our work, we also show that engagement does not positively correlate with user ratings. Instead, what we observe is that lectures with low rating also present low engagement rate. However, lectures with greater ratings can have different engagement rates.

For videos, *watch time* has been used as the main measure for quantifying engagement in the literature, e.g., for YouTube recommendations [13], predicting engagement with videos [40]. For educational content, the median of normalised engagement time (i.e., the percentage of watch time from the total video) has been used as gold standard for engagement [17]. Our work tests several approaches to encoding user engagement.

Most of the related work regarding predicting educational engagement attempts to model learner engagement as a function of the learner’s context (demography, user activity, etc.) [4, 19, 2], as opposed to modelling context-agnostic learner engagement as a function of content-based features of the educational resource, which is our aim. Context-agnostic engagement has been previously studied for video lectures, advocating for qualitative and general recommendations such as keeping videos short [17], using conversational language for lecture delivery [5] and others. These recommendations empower authors to create better educational videos. However, none of these works address the need for automatically identifying the features of highly engaging educational resources, which is imperative for retrieving and recommending educational material at scale.

3. DATA AND METHODOLOGY

This section first describes the dataset built for predicting engagement, together with the set of features proposed in this paper. Then, we introduce the machine learning methods and the feature importance analysis method considered.

To address the research questions outlined in the introductory section of this paper we do the following: i) We study different ways of refining user engagement signals, linking to literature on psychometrics (RQ1). ii) We propose two sets of easily automatable features for predicting engagement (cross-modal features inspired by context-agnostic quality literature and video-specific features) and evaluate the difference of predictive performance between them (RQ2 and RQ3). iii) We construct a large dataset of video lectures and evaluate the performance of the proposed engagement signals and sets of features (RQ2-4). iv) We compare cross-modal to modality specific features, analysing the impact of individual features in the predictive model that presents the most promising performance (RQ4). v) We compare our population-based engagement approach to its personalised analogue to demonstrate its usefulness (RQ5). vi) We

compare the engagement models obtained from dividing the video lectures in two differentiated knowledge areas: STEM (such as technology, physics and mathematics lectures) vs others (such as arts, social science and philosophy lectures).

3.1 Dataset and Features (RQ2-4)

We use data from a popular OER repository, VideoLectures.Net (VLN)¹, a collection of videos of researchers presenting in peer-reviewed conferences. This data is suitable for our aim for two reasons: i) It contains watch patterns about how learners consume lectures, and ii) the lectures are peer-reviewed and hence material is controlled for correctness of knowledge and pedagogical robustness. The transcriptions of English lectures and English translations for the non-English lectures are provided by the TransLectures project². We restrict the final dataset to lectures that has been viewed by at least 5 unique users, leading to the final dataset having 4,063 lectures. These lectures are categorised into 21 subjects, e.g. Computer Science, Physics, Philosophy, etc. Learner engagement labels of the dataset is computed using 155,850 user view log events (video viewing events) created between December 8, 2016 and February 17, 2018. The dataset constructed is publicly available, including different statistics of population engagement and all the cross-modal and video-based features proposed.

3.1.1 Cross-modal Features

We selected a subset of cross-modal and mostly language-based features that are easy to extract from the VLN dataset. The 13 extracted features are shown in Table 1. This set has been selected based on recurring features in the related work [3, 14, 17, 28, 39] and their quality verticals [10] identified in our prior work. The majority of features were extracted using methods and token (word) sets that are found in the prior work referenced in Table 1.

Additionally, we introduce the *published date*, represented by converting the video publication date to UNIX epoch time (in days). In other words, it is the number of days between January 01, 1970 and the lecture published date.

3.1.2 Video-based Features

We also extracted four out of the seven features proposed for analysing educational engagement with video lectures from [17], selecting those features that can be automatised and are objective. These are: i) *lecture duration*, as shorter videos have been shown to be much more engaging; ii) *is chunked*, whether the lecture has been partitioned into multiple parts; iii) a set of indicator variables describing the *type of lecture*, such as tutorial, workshop, etc; and iv) *speaker speed*, measured by the average amount of words spoken per minute. We also include the *silence period rate (SPR)*, calculated using the special tags in the video transcripts that indicate silence. Formally, for a lecture ℓ , this feature $\text{SPR}(\ell)$ is calculated as follows:

$$\text{SPR}(\ell) = \frac{1}{D(\ell)} \sum_{t \in T(\ell)} D(t) \cdot \mathcal{I}(N(t) = \text{"silence"}), \quad (1)$$

where t is a tag in the collection of tags $T(\ell)$ that belong to lecture ℓ , N returns the type of tag t and D returns the du-

ration of tag t or lecture ℓ and $\mathcal{I}(\cdot)$ is the indicator function (returning 1 when the condition is verified, 0 otherwise).

3.2 Quantifying Engagement (RQ1)

Our work focuses on implicit user feedback (most specifically, engagement). Implicit feedback (in the form of number of views, engagement or any other measure that does not require the user to provide explicit feedback) has been used for building recommender systems for nearly two decades with great success [29, 20, 22], as an alternative to explicit ratings, which have a high cognitive load on users and thus are usually sparse. However, implicit signals have other challenges associated with them. For example, implicit feedback is usually positive-only [20] and can contain effects such as popularity bias, i.e., there might be a bias towards more popular items, whereas implicit feedback for other items may be very sparse. There has been several works investigating the relationship between explicit and implicit feedback [12, 34, 42], which we also do through this work.

The main measure that we use to quantify engagement is the **Median of Normalised Engagement/watch Time (MNET)**, as it has been proposed as the gold standard for engagement with educational materials in previous work [17]. To have the MNET label in the range [0, 1], we set the upper bound of MNET to 1. We observed in our initial data analysis that MNET values in the VLN dataset follow a Log-Normal distribution, where it can be seen that most users generally abandon the lecture after a generally low time threshold. We hypothesise this may be because it takes some time to decide whether the content is relevant for the learner. Users that make it after this threshold seem more committed and thus the leaving rate is significantly lower. To address this, as this is usually a problem when using machine learning methods, we applied a log transformation to transform the engagement signal. The final label, *Log Median Normalised Engagement Time (LMNET)*

is computed using the following:

$$\text{LMNET}(\ell) = \ln(\max(\text{MNET}(\ell), 1)). \quad (2)$$

To test if LMNET can be further improved, we compare this approach of encoding engagement to other alternative ways of quantifying and cleaning engagement signals, drawing inspiration from the literature on psychometrics and subjective assessment [21, 38], which focuses on explicit human feedback and assumes that users present cognitive biases and differences, with applications in preference ranking and measuring perception-based qualities, such as engagement. The intuition behind this is that different learners may have a different engagement threshold and scale, similarly as with explicit ratings [21]. We compare different approaches for defining engagement:

1. **Raw LMNET**, as per Eq. (2) which considers that no user differences exist and the marginal over the population can be directly used as gold standard label for engagement, similarly as in [17].
2. **Cleaned LMNET**, for which we test the removal of bot-like users (those users with an average engagement rate less than 5%), which may have a detrimental factor in the median of raw engagement.
3. **Standardised LMNET**, in which we preprocess LMNET per user (subtracting the mean of the user and dividing by the standard deviation), as commonly done with human ratings in order to remove user biases and differences [21]. In this scale, positive values indicate lectures that are more engaging than the mean of the user and vice versa.
4. **Comparative MNET**, in which we exploit the law of comparative judgement and use psychometric scaling to go from user comparative engagement data to a probabilistically interpretable engagement scale [38, 32]. More specifically, we assume that engagement data can only be compared per user (as users may have different biases, thresholds or engagement scales). To do so, we generated a matrix of engagement comparisons (of the type: Did learner i prefer lecture A to B in terms of engagement?), which is used as the input for psychometric scaling, producing a final scale in which distances can be interpreted in terms of probability of greater engagement.

As discussed, the limitation of these approaches is that they disregard the context of the learner and the temporal component that may inherently be present when engaging with educational material. A different measure to encode engagement is found in Wu et al. [40], where the main idea is to compare engagement relative to the length of the video. The authors propose this for entertainment videos. However, we argue against this approach in the case of educational material, as the aim is to take the learner to the desired state in the most efficient way, thus the general recommendations found in the literature of keeping videos as short as possible [17].

3.3 Machine Learning Models (RQ2)

To learn to rank video lectures based on engagement, we evaluate the performance using pointwise ranking models. Regression algorithms predict the target variable in real value space ($y \in \mathbb{R}$), which allows them to create a global ranking of observations based on predictions. We also evaluate the performance of engagement prediction using kernelised models. Kernelisation allows capturing non-linear patterns in data without having to operate in the respective basis. Although it is more computationally efficient than working in the non-linear space itself, it is more computationally expensive than solving the non-kernelised problem. Our choice of kernel for the models is the Radial Basis Function (RBF). RBF kernel is widely used in the literature and has mathematical connections to other popular kernels such as exponential and polynomial kernels [11, 35].

We use two regression algorithms, namely, *Ridge Regression (RR)* and *Support Vector Regression (SVR)* in primal form. We use RR as it is a widely used algorithm for regression [40] and SVR as it has performed well in a similar task in prior work [14]. We also evaluate the performance of the kernelised version of the same two algorithms (with RBF kernel), *Kernelised Ridge Regression (KRR)* and *Kernelised Support Vector Regression (KSVR)*. This allows us to understand if there is non-linearity in the patterns that benefits the prediction task. In all four models discussed above, we employ standard scaling as these models are not scale invariant. L2 regularisation is used to defend against overfitting and multicollinearity [26]. As ensemble techniques have shown to perform well in prior work [39], we also employ a *Random Forest Regressor (RF)* to evaluate its prediction capabilities. This model is also capable of capturing non-linear patterns.

3.3.1 Comparison to Personalised Models (RQ5)

One of our aims is to compare the population-based model to its personalised counterpart. The idea in this case is to test if a common baseline can be assumed for all users. For this, we train the same machine learning models per user, using the features previously proposed.

3.4 Feature Importance Analysis (RQ4)

Understanding how different features influence engageability of materials is vital in educational domain as learners will be guided on life-changing pathways based on these judgements. In a conventional linear model such as RR or SVM, feature importance analysis is straightforward as the weight coefficients reflect the influence of features.

In this paper we use *SHapley Additive exPlanations (SHAP)*, which is a model-agnostic framework that quantifies the impact of features on the model predictions. It reliably estimates feature importance of complex model families such as ensembles [25]. A SHAP value is computed for every feature of every prediction. Given a prediction and a feature, SHAP is computed by averaging how the prediction changes when the feature is present and vice versa. This procedure enables quantifying the contribution of each feature to the model prediction. By plotting all the SHAP values of the prediction data points in a SHAP summary plot, we can identify how each feature influences the prediction. By calculating the *Mean Absolute SHAP (MAS)* for each feature

f over the observations:

$$\text{MAS}_f = \frac{1}{N} \sum_{n=1}^N |\text{SHAP}_{f,n}|, \quad (3)$$

we obtain a more quantitative understanding of feature influence. N is the number of observations.

4. EXPERIMENTS AND DISCUSSION

This section shows the experimental setup and results for the different experiments conducted.

4.1 Experimental Setup

The evaluation of the machine learning models is performed using a 5-fold cross-validation for both feature sets. The performance of different machine learning models with different engagement quantification approaches can be found in Table 2. The performance when video-specific features are added is found in Table 3.

After gaining an understanding of model performance (see results in Table 2), we employ the best performing method and encoding for the rest of the analyses, using a hold-out validation with a train-test split of 70:30 to save computation. That is, the model is trained on the 70% training set and interpreted using the 30% test set. The experiments were implemented using `Scikit-learn` [31], `textatistic` [18] and `SHAP` [25] python packages. The source code in python and dataset are publicly available³.

4.1.1 Evaluation metrics

Pairwise accuracy (Pair.) and *Spearman Rank Order Correlation Coefficient (SROCC)* are the ranking metrics we used to evaluate the ranking performance of machine learning models with different engagement signal encodings.

Identifying models that can rank between video lectures is the core objective of this work. Hence, we devise *pairwise accuracy* as the main evaluation metric. Pairwise accuracy is more intuitive for this task as it represents the fraction of pairwise comparisons where the model could predict the more engaging lecture. Another opportunity that pairwise comparison provides is the ability to restrict the comparisons to subsets of lecture pairs (e.g. lectures that belong to the same subject, lectures that have similar LMNET).

In some of our experiments we also perform misranking analysis and report the pairwise accuracy. Misranking could happen if a subset of examples is systematically difficult to rank. We hypothesize that misclassification happens more frequently as the difference of LMNET between a pair of video lectures gets smaller. That is, the model may struggle to differentiate between two lectures with similar engagement. By doing this analysis, we can also understand the sensitivity of the prediction model to similarly engaging lectures. Obviously, misranking a pair of lectures that are significantly different in engagement incurs a larger cost in terms of user satisfaction than misranking a pair of lectures with similar engagement.

³<https://github.com/sahanbull/context-agnostic-engagement>

4.1.2 Controlling for Topics in Content

The topics covered in the content of the lecture is likely to drive learner engagement. For instance, Data Science lectures can be more popular than Physics lectures leading to easy pairwise comparison predictions between the domains. To test this, we restrict in some experiments the pairwise accuracy calculation to pairs of lectures that belong to the same domain (*subject-specific* column in Table 3) and observe if the accuracy value changes significantly compared to its counterpart metric that considers all lecture pairs in a domain-agnostic fashion.

4.2 Results

This section presents a series of experiments to:

- E1 Analyse the relationship between engagement, number of views and mean star ratings (RQ1).
- E2 Test different machine learning models and engagement signals for the cross-modal features (RQ1-2).
- E3 Study the distribution of engagement with respect to length of materials (RQ4).
- E4 Study the influence of modality-specific features and comparison across subject areas (RQ3).
- E5 Analyse the importance of different features in the model (RQ4).
- E6 Compare the population-based model to its personalised counterpart (RQ5).
- E7 Test if the same underlying model can be assumed for different knowledge/subject areas (RQ6).

4.2.1 E1: Engagement vs Views and Ratings

The VLN data source also has mean star ratings (explicit feedback) for a subset of the considered lectures. It is noteworthy that we only have access to mean star ratings, not to the individual ratings per observer or the number of measurements. As done in previous work, we also analyse the relationship between implicit signals (engagement and number of views) and explicit ratings. This can be found in Figure 1, where we show mean star rating vs MNET and number of views. The SROCC is close to zero, mainly because of the large number of lectures with high rating but low engagement and number of views. We test the correlation for the 4 different versions of engagement considered (raw, cleaned, standardised and comparative), but all achieve similar results, with SROCC close to zero. One conclusion that is clear from the plot in Figure 1 is that number of views, ratings and engagement do represent very different information. For example, it can be appreciated that the variance of MNET and number of views increases with higher ratings, showing heteroskedasticity. This indicates that for low quality resources (with low ratings) engagement is generally low, whereas for resources with higher ratings engagement differs and may be either high or low. This suggests other factors involved in engagement than simply quality perceived by learners. Regarding number of views it seems that the correlation is rather negative, showing that the materials with the highest number of views present very low engagement.

Figure 1: Scatter plots showing the relationship between (i) number of views vs. MNET, (ii) mean star rating for the video lecture vs. MNET and (iii) mean star rating vs. number of views, together with the Spearman’s rank correlation coefficient (SROCC).

Table 2: Pairwise accuracy (Pair.) and Spearman’s Rank Correlation Coefficient(SROCC) of engagement prediction models with standard error from 5-fold cross validation and cross-modal features.

Model	RR		SVR		KRR		KSVR		RF	
Engagement	Pair.	SROCC	Pair.	SROCC	Pair.	SROCC	Pair.	SROCC	Pair.	SROCC
Raw	.705±.011	.581±.027	.707±.000	.586±.000	.715±.004	.607±.011	.714±.007	.604±.019	.723±.009	.625±.027
Clearned	.636±.033	.396±.093	.634±.031	.392±.089	.646±.025	.424±.071	.642±.028	.414±.078	.646±.031	.427±.087
Standard	.603±.035	.302±.098	.600±.035	.292±.100	.609±.035	.315±.099	.602±.025	.297±.071	.611±.035	.323±.099
Comparative	.624±.010	.365±.028	.624±.012	.363±.036	.626±.013	.370±.040	.627±.009	.373±.027	.636±.012	.397±.038

4.2.2 E2: Encoding and Predicting Engagement

Inherently, the task of finding a better engagement signal is very challenging, given the lack of ground truth. In this paper, we first attempt to see if any of these signals present better correlation with star ratings. However, we observe from Figure 1 that engagement is not strongly correlated with perceived quality by users (explicit star ratings) and similar results emerge for different methods of quantifying engagement, meaning it is inconclusive that transforming raw engagement signals strengthens its relationship to explicit perceived quality. Thus, in order to decide on which is the best way of capturing and quantifying engagement, we compare the pairwise accuracy for the four proposed approaches (raw LMNET, cleaned, standardised and comparative). This simply tells us which output target variable is easier to predict given the proposed features. Table 2 presents these results, together with the pairwise accuracy (Pair.) and Spearman’s Rank Order Correlation Coefficient (SROCC) obtained for each machine learning model with the standard error bounds based on 5-fold cross validation. The larger the accuracy value, the better performing the model is.

These results suggest that raw LMNET may be the most appropriate target label, particularly since the proposed features seem to be more useful when building a model for predicting raw LMNET. These results do not contradict the literature, both educational and non-educational, as MNET has been used as the gold-standard way of quantifying engagement. Our experiments thus showed that the use of subjective assessment inspired transformations do not improve the predictive power of engagement signals. This may be because these transformations/correction methods are initially designed to address biases in latent user preferences.

Although similar biases may exist in learners when consuming educational materials (e.g. learner fatigue, different engagement thresholds, language level preferences, etc.) we hypothesise that the most influential driver of engagement is the information content and style of the video.

Another observation from Table 2 is that KRR and KSVR models outperform their linear versions. This suggests that there could be non-linearity in the dataset that is better captured by the kernel techniques. RF seems to be the best performing model providing more evidence that non-linearity plays a significant role.

To show how the accuracy changes when the difference of MNET between two lectures changes, we first compute all the possible differences between pairs of lectures and binarize these pairs into bins of size 0.1 from 0 to 1, finally we compute the pairwise accuracy for each bin. Figure 2 shows how the performance of the model changes based on the *difference of MNET between lecture pairs*. The bars in the figure represent the pairwise accuracy for all the pairs that belong to the same bin. For example, the pairs with largest difference of MNET are predicted correctly with 0.962 accuracy whereas pairs with the smallest difference are predicted with 0.642 accuracy.

Intuitively, a learner might have a similar experience consuming a pair of video lectures that are similarly engaging (at least disregarding the topic), as one is less likely to notice the difference. The black line in Figure 2 presents the *cumulative pairwise accuracy* of the model if we were to assume that the learners are insensitive to noticing the difference of experience for lecture pairs that have a small difference of MNET. The plotted cumulative pairwise accuracy (y-axis)

Figure 2: Bar chart plot showing how the pairwise accuracy changes based on the difference of MNET between lecture pairs

is computed by restricting the comparisons to lecture pairs with a difference of MNET between the lower bound of the x-axis value and 1.0. For instance, the cumulative pairwise accuracy of the model is 0.816 when the learners do not notice the difference when interacting with similarly engaging lecture pairs with MNET difference of $[0.0, 0.2]$. This value is the pairwise accuracy of all the lecture pairs with a MNET difference of $[0.2, 1.0]$.

4.2.3 E3: Length of Materials vs. Engagement

Several studies have shown that features that quantify material length have a significant impact (this is also reaffirmed by our observations in our feature importance analysis in Figure 6 and 7) on sustained engagement with the material [17, 14]. We investigate how the length of the lectures impacts engagement prediction (i.e. if the engagement predictor is naïvely distinguishing between long vs. short video lectures). We first investigate the distribution of total word count in the video lectures (Figure 3), which is directly related to the length. Based on the observed multi-modal distribution, we make two groups, i) short lectures of less than 5000 words and ii) long lecture (see engagement distribution in Figure 4). It can be seen that, as anticipated, the percentage of watch time tends to be shorter for long lectures.

We investigate how median engagement labels are distributed in the aforementioned groups and also how the pairwise accuracy differs among and between the groups. Figure 5 shows that the model is better at comparing between short-short lecture pairs compared to long-long lecture pairs. In the context of VLN dataset, this is good because there are more short lectures than long lectures (Figure 3). Recent findings (e.g.[17]) also encourage authors to make short videos, increasing the likelihood of future video productions being short lectures. MNET distribution in Figure 4 shows that long lectures have a more skewed target value distribution concentrated closer to 0 compared to short lectures

Figure 3: Distribution of word count of video lectures

Figure 4: Distribution of engagement labels for short and long lectures.

Table 3: Pairwise accuracy with standard error via 5-fold cross validation for RF model using content-based features vs. content-based + video-specific features.

Model	Pairwise Accuracy	
	Subject-agnostic	Subject-specific
Content-based Features	.724±.014	.733±.018
Video-specific Features	.744±.011	.755±.014

suggesting that learners tend to consume smaller fractions of long videos. This is likely to be driven by factors beyond other measured features of the lectures, such as limited time availability and short attention span of learners.

4.2.4 E4: Video-Features and Subject Areas

Table 3 shows how the pairwise accuracy increases when restricted to subject-specific comparisons (lecture pairs belonging to the same subject area). This is clearly an advantage, given that most often, an educational recommendation system needs to make choices among sets of resources that belong to the same subject area.

Figure 5: Accuracy bar chart for different types of comparisons using short and long lecture labels.

Table 4: Influence of content-based features on engagement as per their verticals outlined in [10].

Quality Vertical	Feature	MAS	% MAS
Topic Coverage	Word Count	.250	.366
Freshness	Published Date	.107	.157
Understandability	Easiness	.052	.076
Understandability	Stop-word Coverage Rate	.042	.061
Presentation	Normalization Rate	.039	.058
Topic Coverage	Title Word Count	.039	.057
Presentation	To Be Rate	.038	.055
Topic Coverage	Document Entropy	.033	.048
Understandability	Stop-word Presence Rate	.028	.041
Presentation	Conjunction Rate	.019	.028
Presentation	Preposition Rate	.014	.020
Presentation	Pronoun Rate	.013	.020
Presentation	Auxiliary Rate	.009	.013

Table 3 additionally shows how the performance differs when using exclusively the cross-modal set of features and when adding video specific features. The addition of video features increase the performance by approximately 2%. This result shows that there is a compromise in performance when restricting features to cross-modal features although the feature extractors can be reused in a practical scenario.

4.2.5 E5: Feature Importance Analysis

The SHAP value summary plots for content-based and video-specific feature sets are presented in Figures 6 and 7 respectively, where the features are ordered based on overall feature influence using the best performing prediction model (RF). Colour represents the raw feature value (blue low, red high). For example, when the observed values of a feature is red and they have a negative SHAP value, this means that higher values of this feature negatively impact LMNET prediction. Regarding video length, figures validate its impact on engagement, showing that long videos generally present lower engagement and vice versa, with lecture duration and word count being the most relevant features. Prior studies confirm this observation [17, 40, 15]).

Table 4 complements Figure 6 by giving a more quantitative representation of how the influence of different features

Figure 6: SHAP summary plot for cross-modal features.

across the test dataset changes. Higher MAS is associated with more important features. By looking at the five most influential features, we observe that all identified quality verticals (topic coverage, understandability, freshness and presentation) are represented. This observation supports the importance of considering all the different verticals when predicting context-agnostic engagement. The influence of top features is also consistent with results on quality biased information search [3] where it is also found that *Title Word Count* is comparatively less important. Figures 6 and 7 also show the importance of modality-specific features in this prediction task by raising *Lecture Duration*, *Silence Period Rate* and *Speaker Speed* in Figure 7 to high ranks.

4.2.6 E6: Population-based vs. Personalised

We use the 20 most active learners from the VLN dataset to compare the predictive performance of context-agnostic to contextual/personalised models when predicting engagement. Firstly, we train the population-based prediction model using the VLN dataset (outlined in section 3.1) using a 70:30 train-test split. In order to build the personalised model, for each user, we make a similar 70:30 train-test split respecting the temporal order of their individual events. We use the training data to build a personalised model per user using only the cross-modal set of features (no video-specific features). For each learner ℓ , we make predictions on the N_ℓ test events using (i) population-based model and (ii) the personalised model trained on personal events of the learner. We calculate Mean Absolute Error ($MAE(\ell)$) as:

$$MAE(\ell) = \frac{1}{N_\ell} \sum_{n=1}^{N_\ell} |y_n - \hat{y}_n|, \quad (4)$$

where \hat{y}_n is the prediction. As regression models are devised for the task, MAE is a sensible evaluation metric to measure predictive performance of the models. Then we calculate the difference of $MAE(\ell)$ between the population-based and personalised model. Thus, a negative value indicates that the population model is better and vice versa.

Figure 7: SHAP summary plot with video-specific features.

Figure 8, where the y-axis represents the difference in performance between the population-based and personalised, shows that the population-based model has better predictive power when the number of training examples available for the individual learner is limited (≈ 60). This is represented by the green line (at a MAE difference of 0). This demonstrates the usefulness of the population-based engagement prediction model in a situation where the recommender system is in a cold-start phase.

Figure 8: How the difference between Mean Absolute Error (MAE) of population-based and personalised models change with the number of training events per learner. Each data point is an individual learner in the dataset.

Table 5: Pairwise accuracy for STEM and Miscellaneous (Misc.) lectures when trained with subject-agnostic and subject-specific training data

Training Data	Test Data	
	STEM	Misc.
Subject-agnostic	.737	.708
Subject-specific	.732	.704

4.2.7 E7: Individual Models per Knowledge Area

To understand if training subject-specific models can improve on the predictive power of the overall task, we partition the lecture records into 2 categories:

- **STEM:** *Life Sciences, Physics, Technology and Mathematics.*
- **Miscellaneous:** *Social Sciences, Humanities, Arts and Philosophy.*

Then, we compare the performance of the models trained on subject-agnostic (STEM + miscellaneous) and subject-specific (STEM only or miscellaneous only) training data. Table 5 demonstrates that there is little evidence in our results contradicting that a common subject-agnostic engagement model can be assumed across knowledge areas. This is shown in the fact that both training with all knowledge areas or dividing into two, the models obtain very similar test accuracy for each category (.737 vs .732 and .708 vs .704). In fact, the best performance is obtained in both cases by training with the whole dataset. This indicates that in general a common engagement model can be assumed throughout knowledge areas.

4.3 Limitations

Firstly, the model does not include features that capture authority of content or its authors. Authority has been identified as an influential feature and lacking it is a weakness of this model. However, identifying an authority indicator that generalises beyond niche communities (e.g. academia) is challenging yet necessary, especially in the OER landscape where anyone can author learning materials. Additionally, the topic coverage features used in this model (*Word Count*, *Title Word Count* and *Document Entropy*) are relatively naïve, although they are useful. Having better features will likely improve the model. The current work demonstrates promise in predicting learner engagement with video lectures using easily automatable material features alone. More sophisticated features, both cross-modal and modality-specific could lead to higher predictive performance and better understanding of context-agnostic engagement. Thirdly, the engagement model is trained on English lectures and English translation of non-English lectures. This impacts the generalisation ability of the model. The same applies to non-video content as well. More rigorous testing is needed in these fronts. Lastly, given that our dataset only considers OERs and excludes the learning dimension, we highlight that some of our findings may not be directly applicable to other type of educational material. Particularly, given that most of our features are language-based and we disregard visual information, the built models may not generalise to general purpose videos.

5. CONCLUSIONS

Given its timely need, we set out to develop and empirically test the suitability of engagement prediction models for automatically assessing context-agnostic engagement of OERs. Due to the scarcity of publicly available datasets for the task, we sourced a new video-lectures dataset and evaluated how different machine learning models perform on this dataset. In our analysis, we observed that the Random Forest algorithm performs best. We show that cross-modal features provide satisfactory performance, which is a major advantage, since these can be extracted from different resource modalities. Further experiments show that the predictive performance of the model can gain a slight boost in performance by adding modality-specific features. However, the performance does not deviate significantly. Feature analysis showed that lecture length features are the most influential features in predicting context-agnostic engagement, which agrees with prior work. Other moderately influential features come from diverse quality verticals. Our analysis also showed that the model classifies much better when lectures with very different engagement values are compared, as opposed to lectures with similar engagement. This is natural and obviously the negative impact of misranking pairs of similar engagement lectures is relatively small. Our experiments demonstrated that the built model is useful in data scarcity scenarios, e.g. to approach the common cold-start problem in recommender systems. This is both for new users and new content, as our model can automatically estimate the engagement for new material and the model can be used as a prior for when we do not have enough data from a user to build a personalised model. We finally show that dividing the dataset into different knowledge areas (Subjects) and building separate models does not show improved performance, thus validating that a common underlying model can be built for estimating engagement across differentiated knowledge areas.

The proposed context-agnostic engagement prediction model can be beneficial in improving different components of an educational recommendation system. In situations where new content is discovered frequently (e.g. OER landscape [27, 7]), the proposed prediction model estimates *how engaging materials* are prior to exposing them to the learner population. This allows better balancing the risks relating to learner satisfaction with opportunities of having fresh materials. Also, the proposed context-agnostic model can be integrated with a personalisation system in different ways. It can act as a prior that mitigates cold-start problem both on user and content fronts. In systems where personalisation heavily focuses on the topics covered in the materials [9], this model can complement the content-based model by accounting for stylistic and lingual features that go beyond topic coverage.

To further improve the models, future work should address the three main limitations discussed: Future versions of our model should incorporate more sophisticated features. It could be beneficial to include features capturing *authority* and *topic coverage* [10]. In this sense, Wikification [6] can be used to extract covered topics, and data driven authority features, such as [1], can be used to learn a universal author authority score. In the cross-modal front, more features focusing on content understanding, such as topic coherence

and argument strength, can be considered. In the video-specific front, features such as liveliness of the presenter, sound quality and narration quality can be incorporated. Regarding the generalisation capabilities of the model, evaluating the effectiveness of the cross-modal feature set with a bigger video lecture dataset [17, 40] and a text dataset [14] will increase the confidence on the feature set. Similarly, non-English datasets should also be taken into account.

6. ACKNOWLEDGMENTS

The Ebb and Flow of Student Engagement

Measuring motivation through temporal pattern of self-regulation

ABSTRACT

Effective teachers recognize the importance of transitioning students into learning activities for the day and accounting for the natural drift of student attention while creating lesson plans. In this work, we analyze temporal patterns of gaming behaviors during work on an intelligent tutoring system with a broader goal of detecting temporal trends in students' motivation. Findings demonstrate that observing gaming the system behaviors in the near beginning or end of a working session correspond with predictions made by self-regulation theories of ego-depletion and task-switching. Furthermore, analyses provide initial evidence these gaming behaviors are indicative of partial cognitive engagement and session-level influences on student motivation. These findings provide evidence for how temporal fluctuations in students motivations might be inferred through self-regulated behaviors like gaming the system, and how such information could inform better more intelligent tutoring systems that are responsive to cognitive and motivational dynamics during student work.

Keywords

Motivation, Self-Regulation, Measurement, Gaming the system, Ego-depletion, Task-switching, Intelligent tutoring system

1. INTRODUCTION

Many teachers can relate to the struggle of keeping an entire class engaged as the end of the day approaches. Some students may be listening raptly while other have started packing their belongings. Many teachers use class management techniques, such as specific activities in the beginning of class, in anticipation of the difficulties in ramping up the engagement of the entire class [9]. Student motivation appears to vary systematically over the course of a class period. Many good teachers adapt to this reality. It seems appropriate that intelligent tutoring systems should as well.

Student procrastination, the failure to engage in a task in a timely fashion, has a well-established link to student motivations [16]. The nature of the tasks that students have difficulty engaging themselves in can be revealing about their individual goals [15], their perceptions of the value of the task [5], and their beliefs about their abilities to complete the task [21]. Similarly, the context of what drives students to quit can be equally telling about

the same facets of student motivation [20].

Measures of quitting and procrastination leverage the easily observable dichotomy of student engagement, but are there other within-task student behaviors that might similarly indicate motivation? Quitting and procrastination are evidence of students' failure to exercise their self-regulation. In these moments, students are failing to direct their attention towards a less desirable but beneficial learning task, and instead opting to engage in more desirable non-learning tasks. Applying this self-regulation lens, it may be possible to understand student motivation by identifying and analyzing other observable moments during student work where students engage in less desirable behaviors for learning.

1.1 Temporal Dynamics of Self-Regulation

Self-regulation is the capacity to control or direct one's attention, thoughts, emotions, and actions [27]. One of the leading models of self-regulation poses the construct as a reward-based decision-making process [2]. In this model, self-regulation is treated as a series of decisions that seeks to optimize some expected value based on anticipated rewards and costs. Motivation is defined as "the orienting and invigorating impact, on both behavior and cognition, of prospective reward" [2]. Through this theoretical lens, self-regulation decisions are a reflection of student's motivation.

For instance, solving an extra credit problem on the homework may likely push the student's grade from a B to an A for the year. However, the problem will likely take an hour to solve and the student may have to skip soccer practice to find time to complete the problem. Observing the student's choices and behaviors in these critical moments of self-regulation can reveal student's underlying motivation. Prior models of self-regulated learning behavior have focused on the cognitive facets of a given task: its difficulty level [4,7], its domain topic[10], its time cost[6], and its expected value to the student[19]. However, research on self-regulation point to temporal factors that influence decision making.

Task switching research indicates that the exercise of self-regulation imposes a cognitive cost. Once an individual chooses to engage in a task, they do not always appear to be applying themselves with full effort [8]. Additionally, when a person is forced to change tasks rapidly, they are not able to perform at the same level as those given more consolidated spans of time to perform on the same task [11]. These studies imply that students are likely to perform at a reduced capacity when initially beginning work to perform on a task upon initially beginning work,

Ego-depletion models of self-regulation posit that the ability to regulate attention over time may tend to deplete as some time-driven function of an internal and limited resource [23]. Thus,

Steven Dang and Kenneth Koedinger "The Ebb and Flow of Student Engagement: Measuring motivation through temporal pattern of self-regulation" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 61 - 68

motivation may also tend to wane over time leading to an eventual failure to self-regulate.

In this work, we seek to investigate whether these temporal properties of self-regulation are evident in the prevalence of student's failures to self-regulate.

2. Related Works

Measuring self-regulation related constructs is not a new concept in the intelligent tutoring system literature. Prior work has developed a range of models for detecting self-regulation related behaviors.

2.1 Off-task Detection

Some of the earliest work in this space identified off-task student behaviors by identifying large gaps of time between interactions in the log data of student interactions [26]. Inferences on student skill improvement, in addition to whether the students asked for help or attempted a problem correctly/incorrectly following a long gap between interactions determined whether students were off-task while idle.

[18] developed models of mind-wandering, when students' attention and thoughts move off-task, which enabled detection of off-task behavior over much shorter time spans. These models leveraged information from videos and human labels of short time segments to train a supervised model to classify when mind wandering occurs. The features fed into the model included a range of low-level image processing features, facial features, inferred emotions, and temporal features that describe the dynamics of facial features and emotions during a short time interval. [17] extended this work given user self-reports of mind-wandering and included body position information.

2.2 Persistence and Quitting

[4] developed a model of student persistence by analyzing patterns of behavior that included observed student actions contingent on properties of the problems being worked and the student's skill on those problems. In this work, two types of students emerged, where the authors posited that trait level differences in students' capacity for sustained attention lead to differences in learning strategies and persistence during problem solving.

[3] designed a game-based measure of trait level persistence and validated the measure against other existing survey and standard psychometric behavioral tasks. The measure looked at average time on unsolved versus solved problems given a wide range of difficulty levels.

In [7], the authors built models of quitting an educational game. They leverage many features including features of each level of the game, the current state of game progress of the student, and the time in the current level. The final model that emerged from the supervised machine learning process were focused around actions of the student and the state of progress and counts of actions at each level across and within attempts at the level, thus not including any of the limited temporal features given at model training time.

[10] attempted to predict when students would quit reading a given passage. In this work, the authors used semantic features of the reading passages, the recent context of what passage is being read, which passages have been read recently, and both current page and total reading time. Total reading time, a similar proxy to ego-depletion, was found to be a significant contributor to models of quitting with respect to the first page of a passage. The authors

also implicitly investigated the role of task switching by predicting quitting at the beginning of a new passage compared to some other new page within a passage. While some of the data supports a differential impact of task switching and time on quitting, the authors do not explicitly explore how quitting behaviors vary over time.

2.3 Gaming the System

With intelligent tutoring systems that provide scaffolding supports through progressively informative hints and feedback, another behavior tends to arise called "gaming the system" [24]. These behaviors have been identified using information about a series of recent actions such as time spent or the number of recent hint requests and errors, and the characteristics of the problems worked, such as problem section and difficulty in those interactions [12]. Extensive work has attempted to determine what drives gaming behaviors. While some initial work determined that problem context better explained gaming behaviors over trait-like individual propensities to game [25], later work presented the opposite result using a different intelligent tutoring system [22]. A large multi-environment analysis was conducted that compared the types of gaming behaviors observed across urban, suburban, and rural contexts using three different intelligent tutoring systems [13]. The study found that across tutoring environments, students displayed different predominant gaming behaviors, which implies that the lure of certain types of gaming may be different given tutoring environment or problem-type affordances. Similarly, within tutoring environments, students from areas of different population density (eg: rural versus urban) display different predominant patterns of gaming. These differences point to how variation in work environment may have differential anticipated costs to gaming, while the variation within environment but across geographic regions point to possible cultural and thus motivational differences.

2.4 Research Questions

Prior work has developed extensive models of self-regulation behaviors that demonstrate the importance of cognitive, contextual factors, and local temporal factors for influencing student's self-regulation decisions. However, these models have not investigated how self-regulation behaviors might vary systematically over time and how such trends relate to student learning. In this work, we seek to investigate whether the within-session temporal properties of self-regulation are evident in student behaviors and whether these temporal trends are predictive of similar negative impacts on student learning.

Models of the cognitive cost of task switching imply that self-regulation related behaviors such as gaming the system are more likely to occur in the beginning of a work session. Similarly models ego-depletion imply that self-regulation related behaviors such as gaming are more likely to occur after students have been working for some time. We propose to investigate whether models of task-switching and ego-depletion are evident in some changes over time of the probability of gaming the system, a behavioral instance of self-regulation. We then investigate whether lower cognitive engagement as predicted by task-switching theory co-occurs with gaming the system. We follow this with an analysis to determine if failures in self-regulation during critical time periods are indicative of session-level motivation.

3. The Dataset

We utilize an observational dataset [1] including 214 students across 22 classrooms using the Carnegie Learning Cognitive Tutor (CT) in Pre-Algebra, Algebra 1, and Geometry. The tutor

was used approximately two class-periods per week for a full school year. The dataset includes over 2.3M user transactions covering 55, 33, and 26 curricular units divided into 173, 98, and 44 sections across the three courses respectively.

The CT leverages computational cognitive models to provide adaptive problem selection and hint support and correctness feedback to the students. Problems are broken down into a multi-step process, which allows the system to identify independent skills and trace skill improvement over a fine-grained skill model of the domain. On each step, the system is able to provide multiple levels of hint support, with the final level containing the answer to the problem step. The system logs all interactions with the system including problem attempts, hint requests, response accuracy, and problem step time. In this study, transactions for all students over the course of an entire academic year are utilized.

3.1 Measuring Gaming the System

We leverage the model of gaming developed by [14] to annotate transactions as gamed. This model identifies a set of patterns of transactions that experts identify as gamed patterns. A student is determined to be gaming at some time if a series of transactions matches an identified transaction. For instance, a common pattern is when students enter the same or a very similar answer into multiple places without answering correctly, effectively guessing where a calculation result belongs without understanding the organization of the problem. Another common pattern is when students ask for help without taking much time to consider the problem, followed shortly after by an incorrect input. In this case, the student appears to be using the help facility to get an answer but is not taking enough time to use the information provided to derive an answer. The dataset consists of 4.1% of transactions as being labeled as part of a gaming behavior, where the majority of students are labeled as gaming between 3.2 to 4.3% of all observed transactions.

3.2 Aligning Session Time

The data described above only includes transactions after eliminating certain transactions from the original dataset. In order to see temporal patterns, data was excluded from short sessions with length in the bottom 5% of all student session lengths, which was determined to be about 5 minutes. The resulting observed student sessions ranged from 5 minutes to 58 minutes, with a median length of 32 minutes.

One difficulty in measuring ego-depletion with observational data is in controlling for differences in the depleting effects of context. In ego-depletion studies, the task is controlled for and thus can be ruled out to explain observed differences in behavior. In intelligent tutoring contexts. The adaptive instruction will provide variably challenging and types of content and may differentially deplete students across the experiences within the same period of time. To overcome this issue, we leverage the insight that when two students begin working, they might be in similar states relative to their internal thresholds for self-regulation. We also assume that when two students stop working, they are in comparable states. If these two students stop working at different times, it implies similar start and finish attention states, but different depleting effects of context that were experienced over time. In order to account for these differences in uncontrolled contextual factors, we created an additional time measure that aligned individual student transactions within sessions by the percentage of the session time that has elapsed. This alignment facilitates comparison of transactions relative to the start and end of a session, scaled to the session length.

4. Modeling the Effect of Time

Theories of self-regulation imply different models of the effect of time on self-regulation. Attentional shift models posit a cognitive cost of task switching. These costs may cause some tasks to seem more difficult near the beginning of a session. Ego-depletion models imply a reduction of a limited capacity to self-regulation resource over time. These models suggest students may eventually find it difficult to continue in a task and signs of fatigue, such as gaming, may be revealed by an increased tendency to engage in gaming behaviors before finishing working. To test these model implications, we compare five random effect logistic regression models to determine how self-regulation may vary over the course of a session.

We introduce M1 as the baseline model for comparison to determine if any temporal models are significantly more predictive than current best practices as suggested by prior gaming research. This model includes random effects for both student and curricular section to control for the previously established impacts of student and context on student's tendency to game. The remaining four subsequent models similarly control for student and contextual factors while introducing additional factors representing temporal effects.

To define the remaining four models, time is represented along two dimensions. In the first dimension, time is represented as either time elapsed since the student began working or percentage of total working time elapsed, as described section 3.2. Time elapsed models represent the default model informed by both ego-depletion and task switching theories. Percentage of time elapsed models test the hypothesis that such a representation better captures motivation as temporally relative to the most informative moments of student behavior. In the second dimension, time is represented linearly or quadratically. Linear models allow only one main temporal effect to be captured by the model, either a constant increase or decrease in motivation over the course of a session. Quadratic models can capture different effects at the start and end of the session that differ from each other and the middle of the session. All temporal variables are normalized over the full dataset for model interpretation.

M4.1: Baseline – Baseline model for comparison controlling for differences in student's tendency to game and contextual factors across curricular sections, such as average difficulty, that influence gaming.

$$Eq\ 4.1: Gaming \sim (1|Student) + (1|Section)$$

M4.2: Linear Session Time – Extending the baseline model M4.1 by adding a linear term for time-elapsed since the student has begun working

$$Eq\ 4.2: Gaming \sim time-elapsed + M4.1$$

M4.3: Linear Percent Time – Extending the baseline model M4.1 by adding a linear term for proportion of session time elapsed as a percentage of total time observed working.

$$Eq\ 4.0: Gaming \sim pct-time-elapsed + M4.1$$

M4.4: Quadratic Session Time – This model extends model M4.2 by adding a quadratic term

$$Eq\ 4.0: Gaming \sim time-elapsed^2 + M4.2$$

M4.5: Quadratic Percent Session Time – In addition to the random effects in Eq 4.1, this model tests the hypothesis that students self-regulation resources are

$$Eq\ 4.0: Gaming \sim pct-time-elapsed^2 + M4.3$$

4.1 Comparing Models

Table 1. Comparing models of temporal trajectories of student gaming behaviors

Model	BIC	AIC	LogLik
M4.1	434741	434703	-217348
M4.2	434682	434632	-217312
M4.3	434668	434619	-217305
M4.4	434454	434392	-217191
M4.5	454503	434441	-217215

The results of fitting each of the five models are shown in Table 1, including model performance as assessed by AIC, BIC, and log-likelihood. In general, all models with temporal factors outperform the baseline model, M4.1. This implies that temporal information has a significant effect on student's self-regulation behaviors. Additionally, both quadratic models, M4.4 and M4.5, are significantly better than their linear counterparts (Chisq = 179 ($p < 0.001$) for M4.2 vs M4.4, and Chisq = 242 ($p < 0.001$) for M4.3 vs M4.5). Likewise, M4.4 and M4.5 are significantly better than baseline with Chisq = 315 ($p < 0.001$) and Chisq = 266 ($p < 0.001$) respectively.

Figure 1. Number of observations over time in session

Figure 2. Proportion of Gaming Actions by minute

Exploratory plots of proportion of gaming the system transactions over the session support these interpretations. Figure 2 and 4 plot the proportion of transactions identified as gaming the system behaviors across the session over minutes passed or proportion of total session time respectively. As expected from the quadratic fit models, each figure shows an increased proportion of gaming behaviors near the start and end of sessions.

Figure 3. Number of observations over proportion of session time

Figure 4. Proportion of Gaming Actions by Proportion of Session Time Passed

A closer look at the data in Figure 1 reveals that there is a large student participation drop-off near the 43 minute mark. While whole class sessions seem to regularly measure about 60 minutes, students' login and logout times are quite staggered such that 99% of observed student sessions are less than 43 minutes in length. Only 82 out of more than 9800 sessions are observed where students worked continuously for between 43 and 60 minutes. Furthermore, analyzing gaming averaged over each minute of the hour, Figure 2, shows that this dramatic reduction in data is associated with very large and volatile estimates of average students gaming per unit time. Because of the low amount of data observed in the last 17 minutes of sessions longer than 43 minutes, it is hard to draw stronger conclusions about whether students are much more likely to display gaming behaviors if they are able to stay on task longer than 43 minutes, or if the volatility is due to random sampling bias.

A closer inspection of data in Figure 3 also shows some peculiar variability in data at the start and end of sessions. Because session time is divided evenly across the proportion of sessions, there is

no a-priori reason to believe students have more or less frequent transactions at any time in the session. The small decrease in quantity of transactions near the start of sessions implies students take longer on average to complete actions near the start of work. The large spike of activity near the end implies students are taking less time per action shortly before stopping work. In both cases, the data sparsity issue seen in Figure 1 is not likely driving the changes in proportion of gaming seen in Figure 4. The small decrease in activity near the start is associated with the start of a broader downward trend in proportion of gaming behaviors that continues even after activity frequency flattens. The sudden increased frequency of transactions near the end of sessions is associated with a comparable spike in prevalence of gaming the system behaviors. However, because some gaming behaviors are defined by rapid actions in succession, this relationship is expected.

Taking the model comparisons and exploratory data analysis together, this evidence supports the interpretation that there are non-monotonic differences in gaming the system behaviors between the start, middle, and end of sessions.

Table 2. Model coefficients for M4.4 and M4.5

Term	M4.4 - β	Term	M4.5 - β
Intercept	-4.215	Intercept	-4.217
Percent time elapsed	-0.265	Time elapsed	-0.283
(Percent time elapsed) ²	0.231	(Time elapsed) ²	0.252

Comparing the two quadratic models, M4.4 is the best fit model by all 3 measures, BIC, AIC, and Log Likelihood. The model details can be seen in Table 2. The variance in gaming attributable to curricular sections is 0.87. This translates to average gaming attributable to tutor context level factors to range between 0.23% and 8.4% for 95% of sections. The variance attributable to students is much smaller, 0.088. This translates to average gaming attributable to trait-level student factors to range between 0.82% to 2.57%. An inspection of the model coefficients shows that the model predicts the average gaming level at the start of a session, $P(\text{gaming}|t=0)$, is 4.1%. Average gaming at the end of the session, $P(\text{gaming}|t=60 \text{ minute})$, is 18.7%. The quadratic model reaches a minimum observed gaming of 1.3% at 23 minutes into the session.

An 18.7% average probability of gaming after working for 60 minutes appears to be very high given that gaming only occurs overall in the dataset in about 4.5% of all actions. As discussed in the previous exploratory data analysis, the very high gaming proportion observed in the last 17 minutes of sessions is potentially related to the increased volatility created from estimates drawn from small amounts of data. These estimates spike upwards as high as 25%, which corresponds with the dramatic difference between start and end gaming predicted by M4.4. Therefore, the model is reflecting this same artifact of the data.

Inspecting M4.5, the model predicts that gaming is more likely in the start and end of the session. The average probability of gaming decreases to 1.35% by the time the student has worked 67% of the total time. According to the model, we are 3.34 times more likely to observe students game the system near the start of work than near their peak level of focus. Likewise, it is 1.32 times more

likely to observe gaming the system in the moments shortly before students stop work. This model appears to make less dramatic predictions that are more inline with expectations based on overall average frequencies of gaming while not reflecting the same uncertainties as M4.4.

These results support the hypothesis that self-regulation processes have an impact on the average occurrence of gaming the system behaviors over the course of a work session. Students in this data appear to experience decreased motivation near the start of work as would be predicted by the cognitive costs of task switching. Likewise, students appear to show some decreased motivation before stopping work as predicted by ego-depletion theories.

5. Leveraging Gaming for Prediction

The previous analysis has demonstrated that observing instances of weaker self-regulation, such as gaming the system behaviors, support a view of student's dynamic self-regulation capacities over time as predicted by ego-depletion and task-switching theories. This raises the natural question of exactly what observing such lapses in self-regulation implies about a student's internal capacities.

5.1 Gaming Indicates Cognitive Effort

If students are not observed to game the system early in a session, we expect that student motivation is likely higher around this time despite the brief slightly negative impact of task switching. This greater motivation allows students to bring greater cognitive resources to the work relative to days when gaming is observed near the start. When comparing assistance rates in the beginning of a session, the proportion of questions either answered incorrectly or with a request for help on first attempt, a student who is more cognitively engaged should be less likely to make errors or ask for help. Likewise, similar patterns should be associated with assistance rates near the end of students work.

We compared the assistance rates for sessions where a student is observed gaming in the first 10% of the session time (the first 3 minutes for the median session) to assistance rates where no gaming is observed in the first 10% of the session time. To calculate the assistance rate, the raw student transactions are aggregated by problem-step. The outcome of each step is determined by the first attempt at the step. The step is labeled as gaming the system if any of the aggregated transactions are labeled as gaming. Because patterns of gaming generally involve either incorrect or help-seeking behaviors, steps that were labeled as gaming the system are removed before calculating the proportion of incorrect and help-request steps to overall steps observed in the portion of the session.

The assistance rates in the start of sessions are shown in Figure 5 and were found to be significantly lower ($t=-15.22$, $p < 0.001$). The average assistance rate where gaming is observed is 30% ($sd=25$) while the average rate when gaming is not observed is 21% ($sd=26$). Similarly, Figure 6 shows boxplots for assistance rates in the last 10% of sessions. Rates were found to be to be significantly lower ($t=-11.6$, $p<0.001$) with the average session where gaming is observed having a rate of 25.3% ($sd=22$) compared to the average non-gaming session having a rate of 18.6% ($sd=24$).

This simple analysis does not take into account factors such as question difficulty. It is possible that if students are working on difficult content near the start, then they are more likely to make errors and request hints. It also implies that more challenging material may impact how students evaluate the likelihood of

prospective reward given their perceived abilities. This may lead students to believe that applying effort is unlikely to result in experiencing the reward or attempting to apply effort may have greater depleting effects that impact future actions. In either case, it is possible that more challenging material instead of task-switching or ego-depletion explains the relationship between increased assistance score and gaming behaviors near the start and end of work. However, these tests do provide compelling evidence for a possible impact of decreased cognitive engagement on some practice opportunities that can inform future modeling work.

Figure 5. Comparing assistance rate at the start of sessions

Figure 6. Comparing assistance rate at the end of sessions

5.2 Gaming Indicates Motivation Levels

Student's day-to-day average motivation level is affected by factors in the school, in the classroom, and in the student's life more broadly. A death in the family, a fight with a significant other, or a poor grade in another class might be weighing on a student's mind while that begin working. These factors may have a negative effect on student's ability to self-regulate throughout the entire session. If this is the case, these factors will act in combination with the additional impacts of task-switching or ego-depletion at the start and end of the session to impact a student's capacity to self-regulate. Thus, observing gaming the system behaviors at the start or end of a session may also be informative about a student's more general motivational level. In this section, we analyze gaming behaviors throughout the session using information about whether students gamed at the beginning or end of a session to improve predictions of gaming in the rest of the session.

Gaming at the start and end are defined the same as in the previous section. In the data, 29.7% of sessions are observed with gaming at the start while 32.0% of sessions have gaming at the end. Together 49.9% of sessions have instances of gaming the system in the start or end, while only 11.8% of sessions are observed with gaming in the start and end of the session. While gaming near the start or end might be indicative of session level motivational impacts, in this analysis we test whether seeing any gaming at the start or end is sufficiently informative or if start and end are differently informative.

To perform this analysis, we use the best model from the Section 4 analysis, M4.4 the quadratic percent-time-elapsed model. This model will control for the variance due to student and tutor contextual factors, removing concerns about confounds such as gaming at the start may be due to generally more difficult material that makes gaming more likely throughout the session. We compare models that add main effects for whether gaming was observed at the start or at the end as well as linear and quadratic interaction effects. The models are elaborated as follows:

M5.1: Baseline Quadratic Model – the baseline model from Section 4 analysis for comparison.

Eq 5.1: $\text{Gaming} \sim \text{pct_elapsed} + \text{pct_elapsed}^2 + (1|\text{Stu}) + (1|\text{Sect})$

M5.2: Gaming at start/end main effect – M5.1 with a binary indicator variable of whether gaming is observed near the beginning of the session and a binary indicator variable of whether gaming is observed near the end of the session

Eq 5.2: $\text{Gaming} \sim \text{M5.1} + \text{g_start} + \text{g_end}$

M5.3: Combined Gaming at start or end main effect – M5.1 with a binary indicator of whether gaming is observed at either the beginning or the end of the session

Eq 5.3: $\text{Gaming} \sim \text{M5.1} + \text{g_start_end}$

M5.4: Gaming at start and end with linear interactions – M5.4 elaborates on top of M5.2 adding linear interactions with time.

Eq 5.4: $\text{Gaming} \sim \text{M5.2} + \text{g_start:pct_elapsed} + \text{g_end:pct_elapsed}$

M5.5: Gaming at start and end with quadratic interactions – M5 elaborates on top of M5.4 adding interactions with quadratic time terms.

Eq 5.5: $\text{Gaming} \sim \text{M5.4} + \text{g_start:pct_elapsed}^2 + \text{g_end:pct_elapsed}^2$

Comparing M5.2 and M5.3, we see that including separate main effects for gaming at the start and gaming at the end leads to better models rather than combining the information into a single indicator of whether there were any self-regulation failures at either the start or the end of the session. This particular result is worth further investigation to understand how and why self-regulation at the start of a session is differently indicative of student motivation levels compared to gaming at the end of the session.

The results in Table 3 indicate the best fit model is M5.5, the model with start/end gaming information and interactions with linear and quadratic terms. This model is significantly different from the baseline quadratic model ($\text{Chisq}=49.42, p<0.001$) and establishes the informativeness of gaming in the start or end of a session on student's motivation levels through the time that students are working. Details about the model are given in table 4.

Table 3. Comparing Gaming Predictions using Start/End Gaming

Model	AIC	BIC	LogLik
M5.1	434441	434503	-217295
M5.2	422316	422403	-211151
M5.3	427322	427397	-213655
M5.4	419913	420045	-209958
M5.5	418266	418402	-209122

The variance accounted for by section and student level random effects are reduced in comparison to the baseline quadratic model reported in Section 4. The variance attributable to student factors was found to be 0.0789, which translates to an average gaming level of 0.64% to 1.91% for 95% of students. The variance attributable to section level factors was found to be 0.7527, which translates to an average gaming frequency of 0.20% to 5.79% for 95% of sections. This implies that a significant fraction of observations of gaming that were previously explained by section-level factors appears to now be explained by motivational factors indicated by gaming at the start or end of a session.

Table 4: Coefficients for start/end gaming with quadratic interaction terms

Term	β
Intercept	-4.489
Percent time elapsed	1.129
(Percent time elapsed) ²	-1.251
Gamed at start	0.301
(Gamed at start) * Percent time elapsed	-1.480
(Gamed at start) * Percent time elapsed) ²	1.170
Gamed at end	0.356
(Gamed at end) * Percent time elapsed	-0.490
(Gamed at end) * Percent time elapsed) ²	0.900

Table 5 contains the predicted gaming attributable to the main effect terms in model M5.5. The first column describes average predicted gaming at the start of work. The third column describe average predicted gaming at the end of work. Because the model includes quadratic terms, the second column is included to describe the optimum (minimum or maximum) probability of gaming throughout the session. The fourth column describes the odds ratio the chance of gaming at the start relative to the optimum point. The fifth column describes the odds ratio of the chance of gaming at the end compared to gaming at the optimum point. The complexity of the model can make it challenging to interpret, however there are some important trends indicated by the model. If gaming is observed only in the start of a session, gaming is most likely to occur similarly near the start and will reduce over the course of the session as evidenced by the odds of gaming being greatest at the start relative to the end. Likewise, observing gaming only at the end of the session implies that students tend to be well regulated near the beginning of the session and will appear to fatigue over the session until near the end where the odds fall slightly. When students are not observed

gaming at the start or end, there is a corresponding low probability of observing gaming near the start and end. However, over the course of the session, the model predicts that these students become more likely to have slightly reduced motivation until the latter half of the session where attention on the time pressure of the end of class might increase motivation through the end of class. In the limited sessions where students are observed gaming at the start and end, the model predicts a much greater propensity to game throughout, with a 53% chance in the start and a 5% chance near the end.

Table 5: P(Gaming) Main effect predictions given start/end gaming observations

Context	Game (t=0)	Game (t=opt)	Game (t=100)	Start Odds	End Odds
No Gaming start or end	0.35%	1.43%	0.21%	0.24	0.15
Start Gaming	2.14%	2.14%	0.66%	1	0.31
End Gaming	0.18%	2.10%	1.71%	0.086	0.81
Start + End Gaming	53.1%	1.72%	5.1%	30.9	2.98

Taken together, these results support the conclusion that gaming at the start and end of work are indicative of session-level motivational factors influencing student behavior. It also provides initial evidence for separable constructs indicated by gaming at the start versus at the end. Each of these constructs appears to have different degrees of impact on underlying student motivation factors and the resulting decision processes that lead to observable behaviors.

6. Discussion

We have treated gaming the system behaviors as indicators of student's self-regulation. Task switching and ego-depletion theories of self-regulation predict a temporal pattern to student's abilities to self-regulate over the course of a class period. Predictive model comparisons are supportive of the hypothesis that both task switching and ego-depletion are evident in the patterns of student behaviors over each class session. Further analysis indicates that observations of self-regulation behaviors in the start and end of class might be indicative of both temporally immediate degrees of cognitive engagement as well as more session or day-level influences on motivation.

Open questions remain about how student models could operationalize task switching or ego-depletion. The work presented, uses information about the full student session to represent time, though such information is not available to real-time models. This raises the question of how should student's prior behaviors inform a predictive models of student ability to task switch or ego deplete? To what degree do students display consistency in their ability to task switch quickly or manage ego-depletion more effectively across sessions? Over the course of months or years? To what degree are these capacities independent or can correlations be attributable to other latent motivational causes?

We believe these findings highlight the importance of leveraging student models that incorporate temporal variables in the design

of learning activities. Problem selection algorithms may want to be biased for lower challenge or greater interest to overcome negative effects of task switching. Similarly, activities may want to incorporate changes in the rhythm of the activity in order to periodically re-engage student attention as it wains over time. This work exposes an unexplored design space for how educational activities could incorporate temporal effects of student motivation to better enable student learning.

In this work, we introduce the importance of considering temporal factors in addition to content-related cognitive factors to more effectively support students' motivational trajectories within a work session. These findings extend the rich body of work on modeling student motivational and cognitive processes with self-regulated learning. Students are not machines, and they do not always jump immediately into tasks full throttle or have the endurance to work as long as they are asked. Hopefully, a future that recognizes these dynamics can take intelligent tutoring systems one step closer to emulating the capabilities of effective teachers.

Can we Take Advantage of Time-Interval Pattern Mining to Model Students Activity?

ABSTRACT

Analyzing students' activities in their learning process is an issue that has received significant attention in the educational data mining research field. Many approaches have been proposed, including the popular sequential pattern mining. However, the vast majority of the works do not focus on the time of occurrence of the events within the activities. This paper relies on the hypothesis that we can get a better understanding of students' activities, as well as design more accurate models, if time is considered. With this in mind, we propose to study time-interval patterns.

To highlight the benefits of managing time, we analyze the data collected about 113 first-year university students interacting with their LMS. Experiments reveal that frequent time-interval patterns are actually identified, which means that some students' activities are regulated not only by the order of learning resources but also by time. In addition, the experiments emphasize that the sets of intervals highly influence the patterns mined and that the set of intervals that represents the human natural time (minute, hour, day, etc.) seems to be the most appropriate one to represent time gap between resources.

Finally, we show that time-interval pattern mining brings additional information compared to sequential pattern mining. Indeed, not only the view of students' possible future activities is less uncertain (in terms of learning resources and their temporal gap) but also, as soon as two students differ in their time-intervals, this difference indicates that their following activities are likely to diverge.

Keywords

Students behavioral patterns, time-interval pattern mining, interval granularities, sequential pattern mining.

1. INTRODUCTION

The wealth of data that can be collected from a Learning Management System (LMS), mainly the logs of students' interactions with learning resources, provide opportunities to

get a more comprehensive understanding of students learning process: point out engaged or at-risk students, identify the most commonly studied or the most difficult resources, highlight recurrent students' activities, etc. In addition to this thorough understanding, inferences or decisions can be drawn: estimate students outcome, predict students future behavior (including dropout), personalize learning by providing students with information or recommendations, etc. To carry out such understanding, inference or decision, data mining methods have been applied. Pattern mining, that discovers frequent patterns of events in data, is one of these methods and is also used in a large number of application fields. Sequential Pattern Mining (SPM) consists of discovering patterns when data is sequential in nature. These patterns, named sequential patterns, are frequent ordered sequences of events.

In the educational field, a sequential pattern often represents a recurrent sequence of learning resources, that we call an activity [30, 5].

The time of occurrence of events is often part of the data to be mined. However, in most of the cases, the patterns mined do not contain temporal information. Nevertheless, the literature has introduced different ways of including such information in patterns. We can, for example, cite temporal patterns, made of events that are associated with their time of occurrence [36], their duration [8], or the time gap between the events. In [9], gaps between events are grouped into intervals, resulting in time-interval sequential patterns. Since a time-interval pattern conveys more information than its corresponding sequential pattern, they are still the focus of research works [33]. In the rest of the paper, time-interval patterns will be referred to as *ti*-patterns and sequential patterns to as *s*-patterns.

We think that *ti*-patterns are adequate to represent students' activities. Indeed, it is rare that two students perform exactly the same activities, in both learning resources and time, even though they share underlying sequential activities. To the best of our knowledge, no work in the field of educational data mining has focused on the mining of *ti*-patterns.

In this work, we thus rely on the hypothesis that mining *ti*-patterns will contribute to a better view and understanding of students' learning activities. These patterns do not only indicate in which order students interact with learning resources, but provide also information about the temporal relationship between these resources. For example, let us

Oriane Dermay and Armelle Brun "Can we Take Advantage of Time-Interval Pattern Mining to Model Students Activity?" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 69 - 80

consider that students tend to interact sequentially with two resources, each of them being lecture slides. The sequence of both resources represents a sequential activity. Suppose that mining ti -patterns highlights that the time gap between both resources tends to be less than 1 minute for some students and between 2 and 4 hours for others. We can thus deduce beyond this sequential activity that there are two typical behaviors.

To support our hypothesis, we will conduct a study to evaluate if ti -patterns can be actually identified from students' activity data and evaluate to what extent ti -patterns provide additional information about students' activities.

In the following sections, we will first present an overview of related works on sequential and temporal pattern mining (Section 2). We then present the methodology we adopt to support the hypothesis that we draw (Section 3). Section 4 details the experiments we conduct on a real dataset and presents some ti -patterns. The last sections discuss the results (Section 5), then conclude the work and present our expected future work (Section 6).

2. LITERATURE REVIEW

2.1 Sequential Pattern Mining (SPM)

Sequential Pattern Mining is a popular task in Data Mining, introduced by Agrawal and Srikant in [1]. SPM aims to discover frequent sequential patterns in sequential databases. A sequential database D is a set of tuples $D = \{(sid_i, d_i)\}$, where sid_i is the unique identifier of a sequence, and d_i an input sequence. A sequence is an ordered list of events: $s = \langle E_1 E_2 \dots E_x \rangle$, with $E_i \in E$ the set of events. To understand what a frequent sequential pattern is, let us first define what a sub-sequence is. $\alpha = \langle E_1 \dots E_n \rangle$ is a sub-sequence of $\beta = \langle E'_1 \dots E'_m \rangle$ if:

$$\exists [1 \leq j_1 \leq \dots \leq j_n \leq m] \{E_1 = E'_{j_1}, \dots, E_n = E'_{j_n}\}.$$

We also say that β is a super-sequence of α , or that it contains α . Let us now define what the support of a sequence is. The support of α , noted $supp(\alpha)$, is the number of sequences in the sequential database D that contain α . Based on both definitions, we can now define that a sub-sequence α is a frequent sequential pattern, if $supp(\alpha) \geq \delta$, for a defined minimum support threshold δ . We define SP as the set of frequent sequential patterns.

Many SPM algorithms have been proposed in the literature. The most commonly cited ones are *GSP* [32], *PrefixSpan* [26], *SPADE* [37]. All these algorithms use the "apriori property": "If a sequence s is not frequent, then none of the super-sequences of s is frequent." Thus, when one pattern is infrequent, it is not extended. Algorithms can be divided into two main approaches. Apriori-like algorithms (also called *breadth-first* search algorithms), such as *Generalized Sequential Pattern Mining* (GSP) algorithm [32], are the first algorithms that have been proposed. However, these algorithms suffer from scalability problems, mainly due to memory requirements. *Depth-first* search algorithms, which include pattern-growth algorithms, do not suffer from memory complexity, which explains their popularity.

For a couple of years, the most common SPM algorithm is the *Prefix-Projected Sequential Pattern Growth* (*PrefixSpan*) algorithm [26], which is a pattern-growth algorithm, that

relies on projected databases. Projected databases generally reduce the research space as the size of the projected databases decreases at each iteration. However, the main cost is linked to the generation of these projected databases. The pseudo-code of *PrefixSpan* is presented in Algorithm 1.

Algorithm 1 PrefixSpan (α, l, D)

```

1: Inputs:
2:  $\alpha$ : a sequential pattern and  $l$  its length.
3:  $D$ : a sequential database, or a projected database.
4: Outputs:
5:  $SP$ : the set of all frequent sequential patterns.
6: Method:
7: Scan  $S$  to find all frequent items  $b$ .
8: for all  $b$  do
9:   add  $\alpha' = \langle \alpha b \rangle$  to  $SP$  as a new sequential pattern.
10: end for
11: for all  $\alpha'$  do
12:   create the  $\alpha'$ -projected database  $D|_{\alpha'}$ 
13:   call PrefixSpan( $\alpha', l + 1, D|_{\alpha'}$ )
14: end for

```

In the works mentioned below, both the database and the patterns are sequential. However, in some cases, the database can be temporal, i.e. contain information about the time of occurrence of the events. In these cases a sequence is defined as: $s = \langle (t_1, E_1), (t_2, E_2), \dots, (t_n, E_n) \rangle$. where (t_i, E_i) represents an event E_i and its time of occurrence t_i .

When sequential patterns are mined from these databases, time can be either used as an information or order between events, such as in SPADE [37]. The time of appearance of events can also be used as a constraint. For example, in [18] the authors consider that when two consecutive items in a sequence are separated by a time gap bigger than a predefined threshold, they are temporally too distant to represent an association that makes sense. In the same context, [31] discards uninteresting patterns by introducing an interval constraint between items.

2.2 Sequential Patterns Mining in EDM

Sequential Pattern Mining has been extensively used in Educational Data Mining. They are mainly used to identify frequent patterns of students' activities [16, 28], including those that maximize the student learning performance [10]. In [21] SPM is used to study the differences in students' productive and unproductive learning behaviors and thus identify high versus low performing students. A similar objective has been studied on group work systems to understand the success factors in groups behavior [27, 25].

SPM is also used to detect learning problems early, such as in [20] where frequent sequential patterns and flag interaction sequences that are indicative of problems are mined.

One step further, SPM can act as a first step in decision making. In [7], the prerequisite structure of skills is found out, by identifying relations between variables from data. The algorithms developed in [28, 34, 11] provide students with personalized recommendations of learning resources according to their current activity or their learning style. A complete view of various approaches used in educational data mining is presented in [2].

2.3 Temporal Pattern Mining

Temporal information appears to be fundamental in many contexts, hence the number of works interested in the mining of patterns that contain temporal information. Here again, time information can be used in several ways and for different goals: gaps, duration, intervals, etc.

Time information is often used as a gap between events of a pattern. For example in [36], the author considers that each occurrence of a sequential pattern may have different, but close, temporal elements. So, they propose to associate each pair of events of a pattern with a minimal, a mean and a maximal gap values between these events. The resulting model is made of sequential patterns enriched with temporal information, called delta patterns. Similarly, [15] proposes to add temporal information to each pair of events in a sequential pattern. This information, referred to as an annotation, represents a typical gap value between each pair of events of a pattern. In this work, the acceptance of the variation around this typical gap value is automatically evaluated. At the opposite of the previous works, [35] pre-defines a maximal gap value between events of a pattern, which results in temporal patterns called chronicles. [22] introduces an even more constraining frame, the exact gap interval value is imposed. This approach results in a decrease in the support of each pattern. Thus, the number of extracted patterns decreases.

In addition to the gap value, [17] exploits the duration of events. Each element of a pattern is composed of the event, associated with its begin and end timestamps. They propose an Apriori-like algorithm, that uses a hypercube representation of temporal sequences.

More recently, [13] introduces an Apriori-like temporal pattern mining algorithm on multi-modal data streams. At the opposite of the previous works, they do not only use the time gap between events (that represents the duration of the event), but also use the exact starting time of each event.

In line with the works presented above, [6] also manages gap values between events, that are grouped into intervals. At the opposite of other works, the intervals of gap values are predefined, and form "time-interval sequential patterns". A time-interval sequence is defined as:

$$\alpha = \langle E_1\tau_1 E_2\tau_2 \dots \tau_{l-1}E_l \rangle$$

where $E_i \in E$ is the set of events for $1 \leq i \leq l$ and $\tau_i \in TI$ the set of time-intervals. The sequence α is a time-interval pattern if $\text{supp}(\alpha) \geq \delta$. We note TP the set of frequent time-interval patterns of a database D . In their article, the authors propose two algorithms called *I-Apriori* and *I-prefixSpan*, and results show that *I-PrefixSpan* outperforms *I-Apriori* both in computing time and scalability. The pseudo-code of the *I-PrefixSpan* algorithm is presented in Section 2.

A few years later, [19] pointed out that most algorithms of the literature use time information only as a time constraint or to represent the time-interval between successive items [9]. The novelty of this work is that not only the delay between successive items is taken into account, but also between distant items. The "multi time-interval (MI) sequential pattern" models the time-intervals between all pairs of items within a pattern. Two algorithms have been proposed,

Algorithm 2 I-PrefixSpan (α, l, D)

```

1: Inputs:
2:  $\alpha = \langle E_1\tau_1 \dots \tau_{l-1}E_l \rangle$ : a temporal pattern.
3:  $l$ : the length of  $\alpha$ .
4:  $D$ : a sequential database, or a projected database.
5: Outputs:
6:  $TP$ : the set of all frequent temporal patterns.
7: Method:
8: Scan  $D$  to find each frequent pair  $(\tau_i, E_{i+1})$ , where  $\tau_i \in TI$  is the gap interval between items  $E_{i-1}$  and  $E_{i+1}$ .
9: for all  $(\tau_i, E_{i+1})$  do
10:   add  $\alpha' = \langle E_1 \dots \tau_{i-1}E_i\tau_i E_{i+1} \rangle$  to  $TP$ , as a new temporal pattern.
11: end for
12: for all  $\alpha'$  do
13:   create the  $\alpha'$ -projected database  $D|_{\alpha'}$ 
14:   call I-PrefixSpan( $\alpha', l+1, D|_{\alpha'}$ )
15: end for

```

MI-Apriori and *MI-prefixSpan*, that are highly similar to the *I-PrefixSpan* and *I-Apriori* algorithms.

Discovering time-interval patterns has attracted considerable efforts, due to its widespread applications. However, several challenges remain, such as the definition of the adequate set of intervals (whether manual or automatic), including the problem of the granularity of the intervals.

2.4 Temporal Granularities

As soon as intervals are introduced, an issue arises: how to choose these intervals?

[3] proposes to manage different temporal granularities. An algorithm composed of Timed Automata with Granularities (TAGs), associated with heuristics is proposed. TAGs test whether a candidate time pattern appears frequently in a time sequence. The heuristic allows to reduce the number of candidates. [29] focuses on mining periodic patterns, where interesting periods cannot be defined in advance. Two temporal granules are proposed: a fine-grained granule for hourly periods and a coarse-grained granule for daily periods. The time distribution of different time granularities is then estimated by using a combination of Gaussian distribution.

2.5 Temporal Data Mining in EDM

To the best of our knowledge, little use has been made of Temporal Pattern Mining in the EDM field. [23] takes time into account by evaluating the rate at which students change the learning resources of interest. They progressively improve "when" resources have to be recommended to the student. In a learning context, where students can choose both which and when courses and exams to take, the research work presented in [4] uses time information that corresponds either to the "semester in which the exam was taken" or to the "delay with which it was taken". Using this time information, they then study the course and exam schedule that the students take and understand better students' behaviors. Using clustering and comparison, they are then able to suggest improvements to the scheduling of courses and exams of students.

3. DEFINITIONS AND METHODOLOGY

The previous literature review highlights that time-intervals are mainly adopted to model temporal patterns. The algorithm proposed in [6], *I-PrefixSpan*, has the main advantage to consider intervals as a core element of the patterns and the mining process. Intervals are considered as a constraint about the patterns, not as supplementary information about the patterns. It is the main reason why we choose to adopt this algorithm in our work.

We start by introducing definitions that will be used in the following methodology and in the experiments.

3.1 Definitions

Let $p = \langle E_1 \tau_1 E_2 \dots \tau_{n-1} E_n \rangle$ and $p' = \langle E'_1 \tau'_1 E'_2 \dots \tau'_{m-1} E'_m \rangle$ be two *ti*-patterns and $s = \langle E''_1 E''_2 \dots E''_l \rangle$ be a *s*-pattern, with n (resp. m and l), the length of the pattern p (resp. p' and s). Given these patterns, we put the following definitions. Recall that *TP* is the set of frequent *ti*-patterns and *SP* the set of *s*-patterns.

DEFINITION 3.1. *ti*-form of an *s*-pattern

p is a *ti*-form of s , denoted by $isform(s, p)$ if and only if: $(n = m) \wedge (E_i = E'_i), \forall i \in [1 : n]$.
ti-form(s) is the set of *ti*-forms, in *TP*, of s .

DEFINITION 3.2. *s*-form of a *ti*-pattern

s is a *s*-form of p if and only if: $(n = s) \wedge (E_i = E'_i), \forall i \in [1 : n]$. *s*-form(p) is the (unique) frequent *s*-form, in *SP*, of p .
s-form(P) is the set of frequent *s*-forms (in *SP*) of the set of *ti*-patterns $p \in P$.

DEFINITION 3.3. *s*-equivalence of *ti*-patterns

p and p' are *s*-equivalent, denoted $s\text{-eq}(p, p')$ if and only if: $(n = m) \wedge (E_i = E'_i), \forall i \in [1 : n]$.
In other words, $s\text{-form}(p) = s\text{-form}(p')$.

DEFINITION 3.4. Prefix of a *ti*-pattern

p' is a prefix of p if and only if:
 $(m < n) \wedge (E_i = E'_i) \wedge (\tau_i = \tau'_i), \forall i \in [1 : m]$.

DEFINITION 3.5. Extension of a pattern

p' is an extension of p if p is a prefix of p' . We note $ext(p)$ the set of extensions of p that belong to *TP*.
A similar definition can be put for *s*-patterns.

DEFINITION 3.6. Extended part of a pattern

Let p' be an extension of p . The extended part of p , with respect to p' , is the pattern p'' , where $concat(p, p'') = p'$. Thus, $p'' = \langle E_n \tau'_n E'_{n+1} \dots \tau'_{m-1} E'_m \rangle$.

We note $extPart(p)$ the set of extended parts of p , i.e. the set of patterns that, when concatenated with p , result in a pattern that belongs to *TP*.

A similar definition can be given for *s*-patterns.

Example: Let $p = \langle e_1 I_1 e_0 \rangle$, and $p' = \langle e_1 I_1 e_0 I_2 e_1 \rangle$ be two *ti*-patterns. $p'' = \langle e_0 I_2 e_1 \rangle$ is an extended part of p .

DEFINITION 3.7. Pseudo-equivalence of *ti*-patterns

p and p' are said to be pseudo-equivalent, if and only if: $s\text{-eq}(p, p') \wedge (\tau_n \neq \tau'_n) \wedge (\tau_i = \tau'_i), \forall i \in [1 : n - 1]$, i.e. they differ only in their last time-interval.

3.2 Methodology

To support our hypothesis and identify the actual value of a *ti*-pattern model, we define a methodology. More precisely, this methodology aims at identifying if there actually are temporal regularities between students' activities, if managing temporal activities allows to have a better view of students' future activities, and concretely what type of activities are mined. Recall that mining *ti*-patterns is quite new in educational data mining.

We intend to mine *ti*-patterns in a temporal database D , which is a database made up of temporal sequences. A temporal sequence is an ordered list of events (concretely a list of resources students interacted with) and their associated timestamp. Each temporal sequence represents one student's temporal activities and each student is represented by a unique (and long) sequence.

Our methodology relies on four steps, described hereafter.

3.2.1 Determining the set of time-intervals

Recall that although timestamps are discrete values, their precision is so high that relying on time-point (or gap) patterns will probably only lead to infrequent patterns. For example, two sequences that only differ by one second: $\langle (0, E_1) (3, E_2) \rangle$ and $\langle (0, E_1) (4, E_2) \rangle$ will correspond to two different patterns. Grouping gaps to form *ti*-patterns, will increase the support of patterns. In addition, if the intervals are appropriate, the loss of precision about temporal activities will be limited.

So, before assessing the relevance of mining *ti*-patterns, we have to choose the adequate set of time-intervals. Indeed, this set influences the information conveyed.

Let $TI = \{I_0, I_1, \dots, I_t\}$ be a set of time-intervals, where $I_j = [gapmin_j; gapmax_j[$ is an interval that contains all gap values between $gapmin_j$ and $gapmax_j$. Notice that the set of intervals should represent a continuum of gap values from $gapmin_0$ to $gapmax_t$.

We propose to evaluate the quality of a set of intervals TI with 3 criteria:

The fitting ratio. It is the ratio between the number of non-empty intervals and the total number of intervals. A non-empty interval is an interval that is part of frequent patterns. The higher the ratio, the better the set of intervals, as the number of "useless" intervals is low.

The number of intervals. On the one hand, the more intervals, the higher the potential of the model. Notice that when $TI = \{I_0\} = [0 : +\infty[$, it comes down to *PrefixSpan*. On the other hand, using too many intervals increases the complexity of the model. In addition, as there are many intervals, the *ti*-patterns discovered will probably be infrequent. Thus, a good set is a set that has an in-between number of patterns.

The horizon. It is represented by TI , the upper bound of the last interval (the maximal time value of the set of intervals). The larger the horizon, the more complete the model, as it is able to represent long-term recurrences.

From our point of view, the best set of intervals is the one that maximizes the fitting ratio while having a large horizon, with a limited number of intervals.

3.2.2 Comparing sets of s -patterns and ti -patterns

After having fixed the set of intervals, the set TP of ti -patterns can be mined. In this second step, we aim at comparing the set TP with the set SP set of s -patterns, and propose some measures to perform this comparison.

First of all, we propose to study the number of patterns, and their average length, to get a coarse-grained view of the set of patterns. Of course, this measure cannot be used alone, as the goal is definitely not to mine the highest number of patterns.

Second, we study the correspondence between both sets of patterns. Let us start by noticing that the number of ti -patterns cannot be deduced (not even approximately) from the number of s -patterns. A brief explanation follows.

Let s be a frequent s -pattern and $ti\text{-cand}(s) = \{ts_1, ts_2, \dots, ts_k\}$ the set of the candidate- ti -forms of s . Note that ts_i may be infrequent. Two cases arise:

- $|ti\text{-cand}(s)| = 1$. This case occurs when all the occurrences of s have the same candidate ti -form ts . Here, $supp(ts) = supp(s)$, thus ts is also frequent. The corresponding set of s -patterns is noted S^1 .
- $|ti\text{-cand}(s)| > 1$. This case occurs when some occurrences of s have different candidate ti -forms. As a consequence, $\forall i, (supp(ts_i) < supp(s)) \wedge (\sum_{i=1}^k supp(ts_i) = supp(s))$. Here, come three possibilities:
 - $\nexists ts_i, supp(ts_i) > \delta$: there exists no frequent ti -form of s , thus the number of frequent patterns decreases. The associated set of patterns is noted S^0 .
 - $\exists! ts_i, supp(ts_i) > \delta$, thus: $\forall j | \{(1 \leq j \leq |ti\text{-seq}(s)|) \wedge (j \neq i)\}, supp(ts_j) < \delta$. In this case, there exists a unique frequent ti -form of s , the number of patterns remains stable.
 - $\exists(i, j), (i \neq j) \wedge (supp(ts_i) > \delta) \wedge (supp(ts_j) > \delta)$. In this case, there exist several frequent ti -forms of s , the number of patterns increases. The set of patterns associated with both last cases is noted S^{1+} . Based on this, we first introduce the pattern loss measure, that represents the ratio of s -patterns that have no ti -form in TP ($s \in S^0$).

$$pLoss(SP) = \frac{|SP| - |\bigcup_{p \in TP} s\text{-form}(p)|}{|SP|} \quad (1)$$

To complete the pattern loss measure, we define the support loss measure, which applies for any s -pattern that has at least one frequent ti -pattern ($s \in S^{1+}$). The support loss measure evaluates the proportion of "lost" occurrences of s , i.e. that have no correspondence in TP .

Let s be a s -pattern and $P = \{p_1, p_2, \dots, p_k\}$ be a set of ti -patterns, where $isform(s, p_i), \forall p_i \in P$. The support loss of s is defined in equation (2).

$$sLoss(s) = \frac{supp(s) - supp^*(P)}{supp(s)} \quad (2)$$

where $supp^*(\cdot)$ is the support of a set of patterns, defined in equation (3).

$$supp^*(P) = |\bigcup_{p \in P} Seq_id(p)| \leq \sum_{p \in P} |supp(p)| \quad (3)$$

where $Seq_id(p)$ is the set of sequence ids in D , where p is a subsequence. We can see that the support of P is not

defined as the sum of the supports of the patterns in P . To explain this, let us consider $P = \{p_1, p_2\}$, with p_1 and p_2 two s -equivalent ti -patterns.

By definition, the s -form of p_1 (which is the same as the s -form of p_2) occurs at most once in each sequence of D . Similarly, p_1 and p_2 occur at most once in each sequence, but both can occur in the same sequence. As a consequence, the support of P may be lower than the sum of the supports of p_1 and p_2 .

The support loss defined above applies for a s -pattern. If the support loss has to be evaluated on a set of patterns, the average support loss and the associated standard deviation can be used.

3.2.3 Evaluating the impact of time on the set of possible future activities of students

In the following third and fourth steps, we aim to evaluate the benefit brought by time in patterns (through ti -patterns) about the possible future activities of students. To perform this evaluation, we adopt a two-stage approach.

Let p be a ti -pattern and $extPart(p)$ the set of extended parts of p (see Def. 3.6). From the educational point of view, the set of extended parts of a ti -pattern p represents the ti -activities that students frequently do after p .

In this third step, we aim at discovering if managing time allows to reduce the uncertainty about the future activities of students. We compare the set of extended parts of s -patterns and the set of extended parts of their ti -forms.

To conduct this comparison, we propose to use the well-known entropy measure. The entropy of a pattern p represents the "degree of disorder" of the set of its extended parts. From the educational view, given an activity performed by students, the entropy measures the uncertainty of its following activities. The higher the entropy, the more uncertain the following activities. Relying on the entropy is not new in the educational field [38]. Equation (4) presents the way the entropy of a ti -pattern p is evaluated.

$$Ent(p) = - \sum_{j=1}^m prob(p_j) \log_2(prob(p_j)), \quad (4)$$

with $prob(p_j) = \frac{supp(p_j)}{\sum_{k=1}^m supp(p_k)}$ and p_j is one of the m extended parts of p . The same equation stands for s -patterns. Given a s -pattern s , we thus propose to evaluate the benefit of considering time-intervals in this pattern, by evaluating the entropy loss (see Equation 5). Entropy loss of an s -pattern s considers the entropy of s ($Ent(s)$) and the maximum entropy of its ti -form.

$$eLoss(s) = \frac{Ent(s) - \max_{p \in ti\text{-form}(s)} \{Ent(p)\}}{Ent(s)} \quad (5)$$

Several cases may arise. First, $eLoss = 1$. This represents the best case: each of the ti -forms of s has exactly one extension. This means that when managing time in patterns, the future activities are totally certain.

Second, $eLoss = 0.0$. This case represents one of the worst cases: at least one ti -form of s has the same entropy as s . Here, we cannot say that managing time makes the possible future activity less uncertain.

Last, $eLoss < 0.0$. This case represents the other worst case: all the ti -form of s has an entropy higher than s . In this case, considering time decreases the quality of the model. Notice here that the term *Loss* is a misnomer as it may theoretically be < 0.0 . However, this term has been chosen to be coherent with previous measures.

As a consequence, the higher the entropy loss ratio the more managing time in patterns contributes to better estimate students' future activities.

3.2.4 Evaluating the impact of a specific time-interval on students' future activities

This fourth and last step is dedicated to the evaluation of the impact of a specific time-interval of a ti -pattern on its extended parts. More precisely, we are interested in the impact of the last time-interval of a pattern. We focus on the following situation: given two pseudo-equivalent ti -patterns (cf., 3.7), to what extent do their set of extended parts differ?

This evaluation allows to study to what extent two students, who perform the same temporal activity, except about the time of their last activity, do have identical future activities. In other words, is a temporal difference between two activities an indicator of activities that are beginning to diverge?

To perform this evaluation, we first evaluate the proportion of identical ti -patterns between pairs of sets of extended parts, as defined in Equation (6).

$$idExt(PQ) = \frac{\sum_{(P,Q) \in PQ} \frac{|P \cap Q|}{|P \cup Q|}}{|PQ|} \quad (6)$$

with $PQ = \{(extPart(p), extPart(q)) | psd-eq(p, q)\}$ the pairs of sets of extended parts of all pseudo-equivalent pairs of ti -patterns. The higher this proportion, the lower the impact of the last time-interval.

Second, we rely on the proportion of s -equivalent extended parts. This measure also evaluates the impact of the last time-interval on the set of extended parts, but by considering only their sequential nature. The proportion of s -equivalent extended parts is defined in Equation (7).

$$sidExt(PQ) = \frac{\sum_{(P,Q) \in PQ} \frac{|s\text{-form}(P) \cap s\text{-form}(Q)|}{|s\text{-form}(P) \cup s\text{-form}(Q)|}}{|s\text{-form}(P, Q)|} \quad (7)$$

This proportion represents if students tend to share their following sequential activities, even though they differ in their last time-interval. Here also, the higher this proportion, the lower the impact of the time-interval.

Notice that for reasons of readability, $s\text{-form}(\cdot)$ is used here to represent the sequential form of a set of ti -patterns and a set of pairs of ti -patterns.

4. EXPERIMENTS

We apply the methodology described in the previous section to evaluate to what extent mining ti -patterns increases the knowledge about students' activities. We first present the dataset on which the experiments are conducted, then use the 4 steps of the methodology and draw conclusions for each of them. Finally, some mined ti -patterns are displayed.

4.1 Dataset overview and implementation

We collected data from 113 first-year university students, enrolled in a Mathematics and Computer Science Bachelor program and who interact with learning resources on their LMS. We focus on one specific course: algorithms and programming from the Fall semester in 2018. This course is a core course of this program. Diverse online materials are available: slides, exercises for lab sessions, tests, etc.

Most of the students own a personal computer, so they can access the course both during teaching hours (lectures or lab sessions) and after official teaching hours.

The set of events E is made of 35 learning resources, that students can consult. About 50% of these resources are studied during the teaching hours (lectures or lab). The dataset is made up of about 6,300 actions and each student sees on average 56 resources. The dataset spans almost one year, as it includes actions performed not only during the teaching period but also during revisions for the final examination and actions conducted for the retake examination (for the subset of students who failed the final examination).

In the experiments conducted, we use a relative minimum support $\delta = 0.1$. Two algorithms are studied: *PrefixSpan*, to mine sequential patterns and *I-PrefixSpan*, to mine ti -patterns. The source code used for *I-PrefixSpan* algorithm is the one available in [12] (we have slightly adapted the code to our needs). The source code used for the classical *PrefixSpan* algorithm is the one proposed by Gao [14].

4.2 Determining the set of time-intervals

We propose to study two types of intervals: Linear intervals, where each interval has an equal duration, and granular intervals, where the duration of intervals grows with the gap value.

Table 1 presents various sets of intervals studied. For each of them, the number of intervals, the maximal horizon, the fitting of the set, the frequency of each frequent interval, as well as the number of frequent patterns, are displayed. To avoid an artificially high fitting value, we consider that an interval is frequent if its frequency is no less than 10. The frequency of an interval is evaluated as the number of times the interval is used in the frequent patterns.

Before going into the details of the analysis of the set of intervals, we would like to mention that the sets do not all have the same number of intervals, so these values in Table 1 are not directly comparable. In addition, two contiguous granular intervals represent a totally different duration (for example up to 1 hour and up to 1 day), the frequencies are therefore not comparable. Last, notice that the total number of patterns in one set of intervals cannot be explained by the number of patterns of another set. Let us for example consider two sets of intervals and their associated number of patterns. Suppose that the first interval has an average duration twice longer than the second one. A pattern that is frequent in the first set may correspond to either two frequent patterns in the second set, or only one frequent pattern, or no frequent pattern at all (see section 3.2.2).

Let us first consider the three sets of linear intervals. For the two first sets (30 min and 1 hour), the fitting measure is quite low: 8%, which means that the vast majority of in-

Type	Duration	Number of intervals	Horizon	Fitting	Used intervals & associated frequency	# patterns
Linear	30 min	25	12h.	8%	$I_0 : 350,000 ; I_{24} : 1,770,000$	550,000
Linear	1 hour	25	12h.	8%	$I_0 : 549,380 ; I_{24} : 1,843,660$	356,811
Linear	1 day	25	24d.	72%	$I_0 : 90,976 ; I_1 : 42 ; I_2 : 25 ;$ $I_3 : 54 ; I_4 : 119 ; I_5 : 36 ;$ $I_6 : 239 ; I_7 : 189 ; I_8 : 17 ;$ $I_{11} : 14 ; I_{12} : 44 ; I_{13} : 80 ;$ $I_{14} : 17 ; I_{17} : 14 ; I_{18} : 13 ;$ $I_{20} : 36 ; I_{21} : 45 ; I_{24} : 33,298$	37,764
Granular	expon.	16 $I_0 = [0 \text{ sec.} ; 10\text{mn.}]$	8mt.	56%	$I_0 : 17,739 ; I_1 : 79 ; I_8 : 82 ; I_9 : 269 ;$ $I_{10} : 4,278 ; I_{11} : 5,126 ; I_{12} : 6,403 ;$ $I_{13} : 3,693 ; I_{14} : 1,159$	15,754
Granular	human	6 $I_0 = [0 \text{ sec.} ; 1 \text{ mn.}]$	1y.	100%	$I_0(\text{sec}) : 7,706 ; I_1(\text{min}) : 10,551 ;$ $I_2(\text{hour}) : 1,615 ; I_3(\text{day}) : 30,925 ;$ $I_4(\text{week}) : 68,614 ; I_5(\text{month}) : 22,479$	51,025

Table 1: Fitting, examples of intervals and number of patterns for several sets of intervals

tervals are not found in frequent patterns. For example, in "30 min", only the first interval (between 0 and 30 minutes) and the last interval (more than 12 hours) are not empty. We can conclude that both sets of intervals are not good candidates. Caution must be exercised in interpreting this result. It might mean that students do not regularly switch from one resource to another, with a time gap between 30 minutes and 12 hours. It can also mean that the 30 min. time-interval is not relevant. Despite the lack of relevance of these intervals, the number of patterns discovered is important. As only two interval patterns are used, we can consider that *I-PrefixSpan* behaves here almost as PrefixSpan.

The fitting value of the "1 day" set is quite larger: 72%, which means that most of the 25 intervals are frequent. However, the total number of frequent patterns in this set is highly decreased, compared to the "30 min" and "1h" sets (by about 10 times). In addition, many interval frequencies are not so high, some of them being close to the minimal threshold, except the first and last one. This tends to mean that many intervals are not that representative of the data. Moreover, although the number of intervals is quite large (25), the maximal horizon represented by this set remains limited (all together, except the last one, represent a horizon of smaller than a month). Recall that the dataset spans almost one year. Obviously, the horizon can be extended, but it will be at the cost of an even larger number of intervals, as well as an increase in the space and computation time. These results tend to suggest that the set of intervals should contain small intervals for close events (such as suggested by the frequency of I_0 in the 30 min set), and larger intervals for furthest gaps (such as suggested by the frequency of I_{24} in the 1 day set). Thus, a granular set of intervals should better fit the dataset.

We propose to study now two sets of granular intervals. In the first set, the duration of intervals grows exponentially: the duration of an interval is twice larger than the duration of the preceding interval. The fitting of this set is greater than for the two first ones, but smaller than the third one. Nevertheless, the horizon is larger than for all the previous ones (about 4 months), and the number of intervals is decreased. The empty intervals (from I_2 to I_7) tend to represent a gap between 20 min and 10 hours 40 min.

The second set of granular intervals is referred to as "human", the intervals are designed to represent the human natural time: minute, hour, day, week, etc. This set of intervals has a maximal fitting (100%). At the opposite of the "1 day" intervals, that has the highest fitting value till then, the frequency of each interval is quite large (greater than 1,600) and the number of intervals is reduced (only 6 intervals). Besides, the total number of patterns is larger than both the "1 day" and the "exponential" sets.

All these elements contribute to consider the "human" set as the best set of intervals. In this set, time is represented by the {minute, hour, day, week, month, year} intervals. This set has a maximal fitting (100%), covers a large horizon (till a year, which corresponds to the span of the dataset), with a limited number of intervals (6 intervals) and provides a quite large number of frequent temporal patterns. Therefore, in the following experiments, this set of intervals will be used.

Given these elements, we would like to highlight that this set of intervals intrinsically represents the classical rhythm of courses, for example one lecture (or one lab session) is planned each week. The human set of intervals thus allows to mine patterns that represent natural students temporal activities: some students tend to work immediately following a lab session (or a lecture) represented by I_0 or I_1 ; other students wait for some hours in the same 24h, and others work during the week, or even the week after (before the next session) represented by I_4 . It is typically the type of information that we expect to get when we aim at modeling students' activities.

4.3 Comparing s-patterns and ti-patterns

This second experiment aims at comparing sets of *s*-patterns and *ti*-patterns. Table 2 presents both sets of patterns, associated with measures introduced in the methodology. Let us first focus on the number of frequent patterns (line 1). The total number of frequent *ti*-patterns is dramatically smaller than the number of frequent *s*-patterns. The pattern loss is larger than 0.99. This means that the great majority of *s*-patterns has no frequent *ti*-forms, probably due to the spread of occurrences of *s*-patterns over numerous *ti*-patterns. These findings are in line with [22]. In addition,

$\delta = 0.1 (= 11)$	<i>PrefixSpan</i>	<i>I-PrefixSpan</i>
Number of patterns	$ SP = 12, 826, 760$	$ TP = 51, 025 - pLoss(SP) = 0.998$
Average	8	3.8
Max. length	17	8
Example of pattern s, $frequent(s)$ $\wedge \{ \#p \mid (isform(s, p) \wedge frequent(p)) \}$	$s = \langle e_{31}, e_{29} \rangle$ $supp(s) = 26$	$ts_1 = \langle e_{31} I_0 e_{29} \rangle, supp(ts_1) = 1$ $ts_2 = \langle e_{31} I_1 e_{29} \rangle, supp(ts_2) = 10$ $ts_3 = \langle e_{31} I_2 e_{29} \rangle, supp(ts_3) = 6$ $ts_4 = \langle e_{31} I_3 e_{29} \rangle, supp(ts_4) = 3$ $ts_5 = \langle e_{31} I_4 e_{29} \rangle, supp(ts_5) = 4$ $ts_6 = \langle e_{31} I_5 e_{29} \rangle, supp(ts_6) = 7$
Example of pattern s, $frequent(s)$ $\wedge \{ \exists (p_i, p_j) \mid (frequent(p_i) \wedge frequent(p_j)) \}$	$s = \langle e_{22}, e_{33} \rangle$ $supp(s) = 53$	$p_1 = \langle e_{22} I_0 e_{33} \rangle, supp(p_1) = 25$ $p_2 = \langle e_{22} I_1 e_{33} \rangle, supp(p_2) = 22$
Support loss		$sLoss(SP^{1+}) = 0.33$; $std(sLoss(SP^{1+})) = 0.10$

Table 2: Comparison of sets of patterns mined with *PrefixSpan* and *I-PrefixSpan*

we can see in Line 2 that the average length of *ti*-patterns is about twice smaller than the length of *s*-patterns, the same for their maximal length. A first conclusion that can be drawn here is that most of frequent sequential patterns have no recurrences in their time-intervals. This means that students tend to have numerous recurrent sequential activities, and quite less recurrent time-interval activities. However, even though the average length of patterns is divided by 2, *ti*-patterns have a significant length, which means that they do represent a meaningful students' activities. Moreover, a tens of thousands *s*-patterns (about 34,000) have one or more frequent *ti*-forms (about 51,000). This means that for these sequential activities, there are actually temporal regularities. These activities will be studied in more detail in the following section.

Lines 4 and 5 in Table 2 illustrate some examples of *s*-patterns and their candidate or frequent *ti*-forms. Line 4 presents one of the 99.8% *s*-patterns that has no *ti*-form (thus, from SP^0). This pattern ($s = \langle e_{31}, e_{29} \rangle$) has 6 candidate *ti*-forms, but none of them is frequent. We can conclude that no obvious time-interval regularity is observed for this activity. Thus, this activity does not seem to be guided by temporal constraints. We can also observe here that the sum of the support of the *ti*-patterns is greater than the support of their *s*-form *s*. This was mentioned in section 3.2.2.

In the remaining sequential patterns (SP^{1+}) made up of about 34,000 *s*-patterns, 65% of the *s*-patterns have exactly 1 frequent *ti*-form and 91% have 1 or 2 frequent *ti*-forms. The highest number of frequent *ti*-forms of an *s*-pattern is 9, which is quite high. Let us now consider line 5 in Table 2, that presents a *s*-pattern that has several frequent *ti*-forms. This *s*-pattern ($s = \langle e_{22}, e_{33} \rangle$) has a support equal to 53 and two frequent *ti*-forms. Such a pattern occurs with two temporal recurrences, and most of its occurrences have a time gap between 1 minute and 1 day. Such patterns are highly interesting and will also be further studied.

Based on these findings, it is legitimate to ask whether a *ti*-pattern-based model can replace a *s*-pattern-based model. Line 1 gives first indications. Many sequential patterns "disappear" with such a model (more than 99% of sequential patterns have no frequent *ti*-pattern). If the objective is to replace traditional *s*-patterns by *ti*-patterns, a problem of coverage of the model arises. However, if the goal is to iden-

tify which activities (sequential) have temporal regularities, *ti*-patterns are of the highest interest.

Let us now focus on the support loss associated with the complete set SP^{1+} of *s*-patterns that have at least one frequent *ti*-form. $sLoss(SP^{1+}) = 0.33$, with a standard deviation equal to 0.1. This means that on average 1/3 of the occurrences of an *s*-pattern "disappear", i.e. they do not belong to any frequent *ti*-form. We can conclude that among patterns with identified temporal regularities, 33% of the occurrences do not follow this regularity, which may be high.

4.4 Evaluating the impact of time on the set of possible future activities of students

Following our methodology, we evaluate now if *ti*-patterns carry more information than *s*-patterns about future activities of students. As a preliminary remark, we would like to mention that $\#s, eLoss(s) \leq 0$. We mentioned previously that this case would occur rarely, in practice here it does not occur.

In the set SP^{1+} , 71% of the patterns have at least one extension in SP (see Def. 3.5). Let us first consider the 66% of these patterns that have a unique extension. By definition for these patterns, $Ent(s) = 0$ and $Ent(p) \geq 0, \forall p \in ti\text{-form}(s)$. The first Line of Table 3 is an example of such a case. The *s*-pattern $\langle e_{24} e_{27} e_{14} \rangle$ has only one extended part, so its entropy equals zero. It has three *ti*-forms, but only one has an extended part. So, all these *ti*-forms have an entropy equals to zero.

In this case, even if the entropy loss is null, the information about the future activities of students is increased, as only one *ti*-pattern has a frequent extended part.

Let us now consider the 34% remaining patterns, which have more than one extension in SP . The average entropy is 0.84 with a maximal entropy of 7.71. When focusing on the set of their *ti*-forms, the average entropy is 0.35 and the maximal entropy is 6.22. To make entropies as comparable as possible, the average entropy for *s*-patterns has been evaluated only on the set of *s*-patterns that have at least one *ti*-form. We can first notice that entropy of *s*-patterns is globally higher than the one of *ti*-patterns (for both maximal and average values). More precisely, the average entropy of *s*-patterns is 2.4 times bigger than the one of *ti*-patterns. We can thus draw a first global conclusion: managing time in

s-pattern	Examples of extPart(s)	Ent(s)	Examples of $p \in ti\text{-form}(s)$	nbExt(p)	Examples of extPart(p)	max-Ent(p)	mean-Ent(p)
$\langle e_{24} e_{27} e_{14} \rangle$	$\langle e_{12} \rangle$	0.0	$\langle e_{24} I_2 e_{27} I_3 e_{14} \rangle$ $\langle e_{24} I_3 e_{27} I_3 e_{14} \rangle$	0 1	$\langle e_{14} I_3 e_{12} \rangle^{(*)}$	0.0	0.0
$\langle e_1 e_{10} e_{12} \rangle$	$\langle e_{\{3,13\}} \rangle$ $\langle e_{19} e_{\{3,22\}} \rangle$ $\langle e_{12} e_{\{12,19\}} \rangle$	5.49	$\langle e_1 I_5 e_{10} I_1 e_{12} \rangle$ $\langle e_1 I_5 e_{10} I_0 e_{12} \rangle$ $\langle e_1 I_5 e_{10} I_2 e_{12} \rangle$ $\langle e_1 I_2 e_{10} I_2 e_{12} \rangle$	0 1 13 24	$\langle e_{12} I_4 e_3 \rangle$ $\langle e_{12} I_5 e_{\{19,13,12\}} \rangle$ $\langle e_{12} I_5 e_{\{19,13,15\}} \rangle$	4.55	0.78

Table 3: Examples s-patterns with ti-forms, extended parts and entropy values. (*) The corresponding extension pattern is $p'' = \langle e_{24} I_3 e_{27} I_3 e_{14} I_3 e_{12} \rangle$.

patterns allows to decrease the uncertainty of students' future activities.

We will now compare the entropy of each s-pattern, with the entropy of its ti-forms (through $eLoss$). In 68% of the cases, the entropy loss between the s-patterns and their ti-forms is higher than 0. This means that when considering a temporal student activity, in 2 cases out of 3, the future activity of this student is less uncertain than when managing his/her sequential activity. These 68% are divided into 51% with a loss equal to 1, which means that future activities become certain. 17% of the cases have a loss between 0 and 1. The average entropy loss on all s-patterns is quite high: $eLoss = 0.4$. Roughly speaking, the future activities of students are on average 40% less uncertain when managing time in patterns, which is highly promising.

Thanks to these experiments, we confirm that managing time-interval patterns allows, in most cases, to have a better view of the following activities of students. In addition, for a significant number of activities, future activities are now totally certain.

Let us now focus on an example presented in the second Line of Table 3. The s-pattern $s = \langle e_1 e_{10} e_{12} \rangle$ has many extensions in SP and many ti-forms, among which many of them have extensions. Notice that although the entropy loss is low (the maximal entropy of the ti-forms is 4.55), on average it is significantly lower (0.78). In this specific case, $eLoss$ measure is not that representative of the difference in entropy, the entropy decrease is probably higher than the $eLoss$ value.

4.5 Evaluating the impact of a specific time-interval on students' future activities

The experiments conducted here fall within the scope of the last step of our methodology. They aim at evaluating to what extent two students who perform a similar activity (both in terms of resources and time-interval) and who only differ in their last time-interval, have the same future activities. In the experiments conducted, we will only focus on patterns made up of at least 3 events (and 2 time-intervals) to ensure that the patterns can be considered as activities.

In the set PQ composed of $|PQ| = 9,510$ of pseudo-equivalent pairs of patterns (cf., Definition 3.7), 25% of the extended parts of a pattern of any pair are also part of the extended parts of the other pattern (sequentially and temporally identical). 11% additional pairs have sequentially identical extended parts. This highlights that even when two ti-patterns

differ in their last time-interval only, this small difference leads to a significant difference in their sets of extended parts. In terms of students' activities, this means that when two students make exactly the same activity, except on the last time-interval, their following activities mainly differ: not only in terms of temporal activities but also in terms of their sequential activities. We can conclude that the last time-interval highly influences students' future activities and that it may be viewed as an indicator of activities that are beginning to diverge.

Experiments conducted in both previous sections confirm that ti-patterns contribute to the increase of the information about students' future activities whereby the uncertainty of this future is reduced. As a consequence, we can say that time is an important information in students' activities.

4.6 Interpretation of ti-patterns

In this section, we present examples of frequent ti-patterns, in an understandable format to better analyze and understand students' activities.

The events ids in patterns are replaced by their type and an id. Lec_n will refer to the slides associated with the n^{th} lecture; $Glos_n$ will be the n^{th} glossary resource; Stx_n a syntax resource; Sum_n will be a summary resource; Lab_n a resource that contains exercises that are studied during lab sessions (exercise sheets); FA_n are facultative additional exercises; finally Ad is the advise resource. The time-intervals are noted $(I_s, I_{mn}, I_h, I_d, I_w, I_{mt})$, which refer to seconds, minutes, hours, days, weeks and months.

Given that the longer an activity, the more information it contains, we will preferably focus on the longest ti-patterns.

Activities made up of temporally close events

Let us start by studying activities that contain only the "seconds" time-interval (i.e. events with a maximal gap of 1 minute). This will allow us to have a better view of the type of activities that are performed on the spot. First, the corresponding activities tend to be made up of specific types of events: they are a mix of glossary, syntax, advertisement and lab resources. Second, the maximum length here is 7, which means that there are actually long recurrent "quick" activities made by students. Third, when analyzing the activities, we can remark that they all have a similar skeleton: students generally start by looking at the following resources (in any order): $\{Sum_5, Stx_3, Glos_3\}$, then study one or more Lab exercises and finally consult an advice page. Let us for example present a ti-pattern of length 7:

$\langle Sum_3 I_s Stx_3 I_s Glos_3 I_s Lab_1 I_s Lab_2 I_s Lab_3 I_s Ad \rangle$

Such patterns can be interpreted as follows: they represent

typical activities performed when preparing an exam. Not only several *Lab* sheets are studied, but also before these resources, students have a quick look at the syntax, glossary, and summary of the lectures. They finally consult the advice page. In such patterns, students interact with resources within a short time, including with the lab sheets.

Activities made up of I_h time-intervals

Let us now focus on patterns that use the "hours" time-interval, where patterns are made up of events with a gap value between 1 hour and 1 day. Here again, we identify a skeleton shared by most of the *ti*-patterns:

$\langle Lab_{\{1,3\}} I_h Lab_{\{2,3\}} I_h Lab_{\{2,3,4\}} \rangle$, where $Lab_{\{1,3\}}$ means either Lab_1 or Lab_3 .

These patterns highlight that some students tend to work sequentially on several exercise sheets. The gap being between 1 hour and 1 day, tends to mean that students dig deep into their works: they spend some hours to perform each exercise sheet.

Other intervals

We have performed a similar study on other time-intervals. For each of them, we also identify skeletons shared by almost all the patterns.

An interesting conclusion that can be drawn from these findings is that for any given time-interval, typical long activities are made by students, that do all have the same skeleton. More importantly, when comparing skeletons between time-intervals, they are totally different. We can thus conclude that the type of activity performed is strongly linked with the "rhythm" of the activity. Here, "rhythm" means a time-interval granularity shared by all gap between all events of the activity.

Last, when studying the timestamps associated with each occurrence of the activities presented above, there is no specific period associated: they are performed at any moment in the semester. For example, when considering the first example given, that is mainly related to the 3^{rd} lecture, we found similar patterns for the 1^{st} , 2^{nd} , etc. lecture resources.

5. DISCUSSION

While traditional studies emphasize that students have typical sequential learning behaviors (identified by frequent sequential patterns), this study further emphasizes that for specific activities students work with temporal regularities. Based on the experiments conducted in the previous sections, we initiate a discussion.

The results have highlighted that among the sets of intervals tested (linear and granular), the one that represents the human natural time is the most relevant one, at least for the dataset used in the experiments (see section 4.2). In addition to outperforming other sets of intervals according to predefined measures, this set conforms to the scope of application: the duration of most of the lectures or lab sessions is about one hour, two successive lectures tend to occur each week, etc. So, the interpretation of the discovered patterns is enhanced. Of course, many other sets of intervals remain untested and may be more adequate. Besides, an automatic approach that learns the optimal set of intervals could be tested, as in [24]. However, this would be at a significant additional computational cost, without any guarantee of applicative interpretability of these intervals.

As expected, a high number of sequential patterns have no frequent *ti*-form. In the experiments conducted, we have even highlighted that most of the sequential activities have no temporal regularities. This results in a high number of "lost" patterns, which can be problematic, in case we are interested in both frequent *ti*-patterns and *s*-patterns. A solution could manage both types of patterns: sequential students' activities mixed with temporal students' activities. This solution would not only maintain the coverage of the model, thanks to sequential patterns but also manage time, thanks to temporal patterns, when suitable. Here is an example of such a pattern: $\langle E_2 E_{27} I_1 E_{13} \rangle$. This pattern means that many students consult E_2 then E_{27} (whatever is the time-interval), then between 1 minute and 1 hour later they do consult E_{13} .

Focusing on *s*-patterns and their various frequent *ti*-forms can help to highlight different learning approaches adopted by students. For example, an activity done with a gap lower than 1 minute between its events may represent the fact that the associated students are used to first download all the resources and then work offline. The same activity with a time gap between 1 minute and 1 hour may reflect that students do work online, they do not access a resource before finishing the previous one. So, in addition to highlighting the diversity of activities of students, *ti*-patterns are also a way to identify students' learning practices. One can foresee that these patterns could be used as input information for many works such as those that focus on students' engagement.

6. CONCLUSION AND FUTURE WORKS

The study presented in this paper highlights the relevance of using time information when mining patterns of students' activities. A time-interval pattern mining approach, through the *I-PrefixSpan* state-of-the-art algorithm, has been adopted to conduct this study.

The experiments conducted have pointed out that the nature of the set of intervals used highly impacts the representativity of the model and that the set of intervals that represents the human natural time is adequate. We also found that most of the sequential students' activities do not correspond to any time-interval activity. However, for other cases, managing this time-interval provides a better view of the future possible students' activities, thanks to temporal indicators. Moreover, results show that a single time-interval difference between two events of two patterns sequentially equivalent results in significantly different subsequent activities.

We thus confirm our hypothesis: temporal information is highly promising for a more precise modeling of students' activities. One additional experiment has illustrated some frequent students' activities both temporal and sequential. It has put forward that, by looking at some specific time-intervals, we can understand what activities students often perform instantly or throughout a longer period.

The work we have conducted provides a first step towards longer-term research. One of our future goals is to provide students with recommendations of educational resources. By relying on *ti*-patterns, we are confident that not only the accuracy of the recommendations provided to students will be increased but also that these patterns will give indications about the right time to propose recommendations to students.

ABSTRACT

As programming must be learned by doing, introductory programming course learners need to solve many problems, e.g., on systems such as 'Online Judges'. However, as such courses are often compulsory for non-Computer Science (non-CS) undergraduates, this may cause difficulties to learners that do not have the typical intrinsic motivation for programming as CS students do. In this sense, contextualised assignment lists, with programming problems related to the students' major, could enhance engagement in the learning process. Thus, students would solve programming problems related to their academic context, improving their comprehension of the applicability and importance of programming. Nonetheless, preparing these contextually personalised programming assignments for classes for different courses is really laborious and would increase considerably the instructors'/monitors' workload. Thus, this work aims, for the first time, to the best of our knowledge, to *automatically classify the programming assignments in Online Judges based on students' academic contexts* by proposing a *new context taxonomy*, as well as a *comprehensive pipeline evaluation methodology* of cutting edge competitive Natural Language Processing (NLP). Our comprehensive methodology pipeline allows for comparing state of the art data augmentation, classifiers, beside NLP approaches. The context taxonomy created contains 23 subject matters related to the non-CS majors, representing thus a challenging multi-classification problem. We show how even on this problem, our comprehensive pipeline evaluation methodology allows us to achieve

an accuracy of 95.2%, which makes it possible to automatically create contextually personalised program assignments for non-CS with a minimal error rate (4.8%).

Keywords

non-CS majors, NLP, contextually personalised assignment lists

1. INTRODUCTION

Introductory Programming (often known under the label of 'CS1') classes are now-a-days often compulsory for undergraduate courses that do not have computing as their major [10, 15, 20, 23]. CS1 is delivered to students majoring in, e.g., mechanical engineering, economics, etc. - whom we collectively name here 'non-CS students'. It is common in such cases to find students with difficulty in interpreting assignment texts, due to the lack of affinity with the area of the problem [22]. As a result, many of these students may be discouraged by CS1, as they fail to see the purpose that programming can have in their professional lives [10, 17, 23].

Moreover, programming must be learned by doing and, hence, learners need to solve many problems [11, 17–19, 27]. In this sense, 'Online Judge' systems can influence positively the learning process of non-CS students [12, 18, 20, 25], as systems which allow students to submit programming assignments and provide real-time automatic code correction. As Programming Online Judges (POJ) have large numbers of problems registered in their problem banks [25], in principle, there would be plenty of problems to select from, for both students as well as teachers, allowing for a mass personalisation - where one teacher could cater in parallel for the needs of many students. Nonetheless, the problems available on these systems often are collected or scraped from various environments that do not provide labelling [27], and thus it is laborious to find appropriate problems for non-CS students. This is more so the case, as the number of programming exercises is constantly increasing [25, 27]. Therefore,

Samuel Fonseca, Filipe Dwan Pereira, Elaine H. T. Oliveira, David Fernandes, Leandro Carvalho and Alexandra Cristea "Automatic Subject-based Contextualisation of Programming Assignment Lists" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 81 - 91

the automatisisation of the categorisation of problems based on subject matter is becoming vital, to support instructors who teach computer programming disciplines. To illustrate, undergraduate students of Economics would be more familiar with an *if-then-else* problem using terms such as “interest rates” or “importation of goods” instead of a problem on the “growth of cells”, which may be completely out of their comfort zone. Thus, we raise the following research question:

How can we extract the subject matter from programming problem statements, to automatically match programming assignment lists to non-CS courses?

Our main contributions with this paper are thus:

- Proposing a new, *wholistic methodology pipeline for the POJ contextual labelling problem*, allowing to compare a variety of cutting edge shallow and deep learning models, to experiment with the most recent data augmentation techniques (with or without augmentation), NLP (based on BERT, Word2Vec, Glove), classifiers (based on BERT, Random Forest, SVM, XGBoost, GaussianNB, GradientBoosting, ExtraTree, Sequential DNN, CNN, RNN) and validation.
- Extracting, for the first time, to the best of our knowledge, automatically and precisely, subject matters related to non-CS courses; we do this by using cutting edge NLP techniques on the statements of assignments available in a home-made online judge CodeBench¹ used with fifteen non-CS major programmes.
- Proposing a *subject-based contextualisation taxonomy* to map subject matters to non-CS courses, where CS1 is compulsory.
- We thus are enabling the contextual personalisation of programming assignment lists for non-CS courses.

2. RELATED WORK

There are many studies tackling the challenge of teaching introductory programming to non-CS students, based on a variety of angles. To illustrate, [10] employed collaborative scenarios to enhance teaching and learning programming in non-CS courses, whilst [23] used an approach involving games and media. [15, 24] show that English-like (natural language) syntax can help non-CS students overcome the difficulties in learning programming syntax. Furthermore, a recent study [21] explains that effective motivational educational design can enhance introductory programming students and teacher engagement. Despite these works representing a move towards improving non-CS students engagement, linking text collections to general or domain-specific knowledge is essential [1, 5]. More specifically, [14] argue that students’ experiences of the learning context have important implications for teaching and learning. Nevertheless, none of these aforementioned studies take the context of the problem into account. Especially untouched is the issue of contextualisation of the problem statements, ensuring that problems introduce only the degree of difficulty required to progress

¹<http://codebench.icomp.ufam.edu.br/index.php>

in the programming knowledge and not additional complexity from strange contexts for the current learner (such as a geology context for economy students, etc.).

Online judges (POJ) are increasingly being used to support introductory programming (CS1) classes. Via such environments, teachers can provide problems to be solved and students can submit their code and receive immediate feedback [9, 18, 25]. One of the issues of these systems is that, in general, the problems available are not categorised based on subject matter, topics, context, major, etc. In this sense, there are two recent works [3, 27] which tackle the problem of topic extraction from such problems. In these studies, topic extraction is used for grouping problems in terms of their related programming knowledge components, concepts or skills. For example, a problem that can be solved by using graph algorithms, such as breadth-first search, flood-fill or topological sort, can be classified into the graph category. Notice however that the target audience of these studies are more experienced POJ users. Instead, here we are not interested in categorising problems based on advanced topics.

In fact, we tackle, for the first time, to the best of our knowledge, the challenge of extracting the subject matter from programming problem statements available in POJ systems used in introductory programming, in order to improve the teaching and learning process of CS1 for non-CS courses, by matching problems to non-CS majors.

3. EDUCATIONAL CONTEXT

In this paper, we use as study base, as said, the CodeBench Online Judge environment, which is self-designed and implemented, as it allows us the freedom to add the changes inspired by our research results. Thus, we analyse here running the Introductory Programming (CS1) course at the Federal University of the Amazonas, via this self-designed POJ, which is delivered to 15 non-CS undergraduate degrees across the university. These courses are divided into 5 major areas: Mathematics, Physics, Engineering, Statistic and Geology. Three of the degrees belong to Mathematics, 2 to Physics, 8 to Engineering, 1 to Statistics and 1 to Geology. Figure 1 illustrates this configuration.

As Figure 2 illustrates, during the CS1 course, students in our environment typically solve 7 assignment lists with problems of increasing difficulty, using the Python programming language. They are allowed to solve the problems with an unlimited number of submission attempts, as long as they meet the deadline for solving all problems on a given list. The exercise lists always precede an exam on the same programming topic, both carried out in the Online Judge. Each list has an average of 10 questions, and the tests have 2 questions. We call a list together with its exam a ‘session’, where each session addresses a specific programming topic. Altogether, the course thus is formed of 7 sessions, that is, 7 programming topics are covered during CS1. Each session lasts on average 2 weeks.

During the 7 sessions, students work on the following programming topics: *Sequential*, *Composite conditional structures*, *Chained conditional structures*, *Repeating structures by condition*, *Repeating structures by count*, *Vectors* and *Strings* and *Matrices*. Before the 7 sessions, students have a

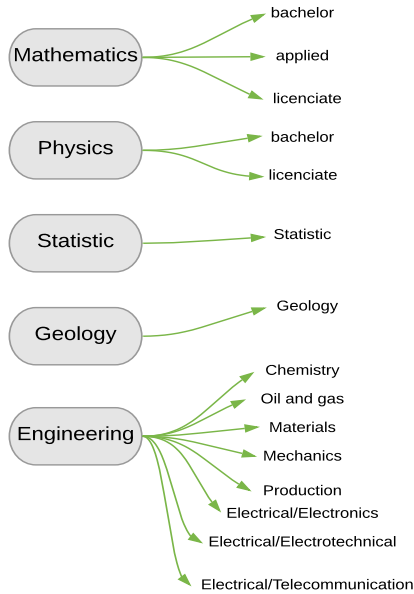

Figure 1: non-CS undergraduate courses at the Federal University of the Amazonas

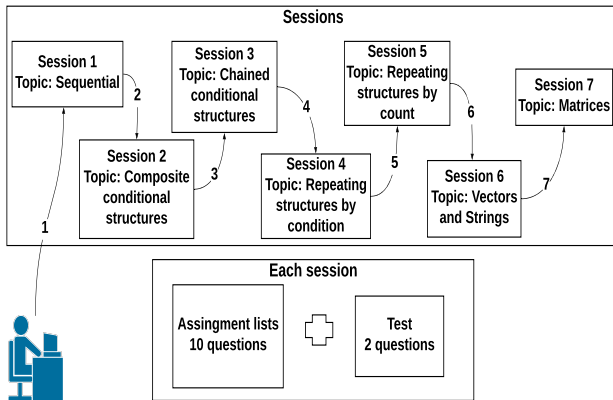

Figure 2: CS1 course configuration

first week to get used to the Python programming language, where they learn about *Variables* and *Single Operations*.

Whilst, in our online judge, problems are well structured based on these programming topics as above, they lack a clear division based on the contexts (here, related major areas) in which the problems are to be delivered. Please also note that, although the sessions are ordered by their increasing difficulty, the topics they are addressing are somewhat unrelated. Moreover, this increase in difficulty is typical for any CS1 course, be it offline or online.

Thus, our POJ is generic enough and is hence a good environment in which to research approaches to automatic classification by contexts, based on the statements, to build context-based personalised assignment lists, towards ul-

timately enhancing the engagement of non-CS students in their learning process.

4. DATA

The database in our Online Judge system consists of 986 programming problems in the CS1 discipline. As said, the statements in the database were initially not categorised by context; thus, we proceeded to create a labelled corpus, by manually classifying the contexts of each statement, to further use to carry out the experiments.

As labels, we adopted in this research contexts extracted from Zanini and Raabe’s definitions [26], which show that the context of problems plays an important role for novice programming students. Their study manually analysed the contexts of 428 programming problems statements used in introductory programming (as in our case) offered to 51 undergraduate courses. As a result, they found 20 possible contexts for these problems, as follows: mathematical, commercial, person, school, human resources, research, banking, physics, production, sport, computational, traffic, date and time, environment, tax, safety, consumption, population, others, and gamble.

We thus started with their proposed labels to annotate our problems. However, there were some groups of statements that could not be mapped over the above contexts. Moreover, the context “others” is too general and provides no real information. Given that, we removed the context “others” and propose here some additional contexts, as part of our contribution, in order to annotate our larger set of statements. As a result of the above process, we produced a total of 23 contexts, which we grouped together in a *new CS1 Context Taxonomy*, which is described in Table 1. This includes the following contexts, as contributions of our research: *Games, Movies and Series, Chemistry* and *Geography*. In addition, the table shows the number of statements for each context labelled and used in this research, the description of the contexts as well as the undergraduate courses that may have a high connection with the context.

It is worth noting that we performed a statistic test that measures inter-annotator agreement to validate if our annotation process was conducted properly. To do so, we used Cohen’s kappa (k) [4], which shows the level of agreement between two annotators on a classification task. As a result, we achieved a $k = 0.961$, which is considered almost perfect agreement [2].

5. METHODOLOGY

Figure 3 illustrates the proposed evaluation methodology pipeline used in the experiments of our research. We create here a unique, comprehensive pipeline, studying various combinations of the most popular and successful bleeding edge state-of-the-art techniques for natural language processing (NLP). The following subsections explain each step of our methodology.

5.1 Data augmentation

The data augmentation stage consists of balancing the training data by paraphrasing it, using the pre-trained model BERT [6]. Importantly for our task, this allows for *context-*

Context	Focus of the Statement	non-CS course	N
Mathematical	resolution of purely mathematical problems, without this being applied to another context	Mathematics and Engineering	261
Commercial	handling of products, goods, such as buying and selling, calculation of commission, provision of services	Economy	120
Games	game application, be it a virtual game or even a table game; for example, in the database there are games of naval battles, as well as video games	Digital games courses	96
School	to solve a school problem, such as averaging, passing or failing verification	Pedagogy	79
Traffic	related to the driver, car, mileage, accidents	All courses	43
Sport	some activity involved with sport, such as running, football, classification	Physical education	42
Physics	resolution of purely physical problems, without this being applied to another context	Physics and Engineering	36
Banking	related to bank transactions, investment, balance, withdrawal, deposit, stock exchange	Economy	35
Human Resources	problem related to human resources, such as salary calculation, data related to employees, calculation of bonuses, recruitment and selection of employees	Sociology and Psychology	35
Movies and TV Shows	problem situation in a film or TV shows. To illustrate, there are questions from the movie <i>Harry Potter</i> about potion calculation	All courses	30
Population	problems on population data, such as birth rate, mortality rate, population growth; referring to either human or animal population	Statistic	25
Chemistry	purely chemical problems, without this being applied to another context	Chemical engineering	23
Person	problems with elements directly related to a person, like weight, height, sex	All courses	22
Date and time	calculation of date or time, calculation of day, verification of month, conversion of hours, minutes and seconds, time interval	All courses	21
Safety	control access, password verification, data security, encryption, validation	Software engineering	20
Research	providing statistical data of opinion polls	Statistic and Journalism	18
Environment	relating to environmental issues, such as pollution, temperature	Environmental engineering	18
Health	related to issues of fighting diseases	Medicine	17
Consumption	calculation of water, electricity or telephone-related consumption	Economy	16
Geography	resolution of purely geographical problems, without this being applied to another context	Geology	11
Production	related to the production of products, the quantity produced, production value, origin of the products	Production engineering	7
Computational	computational issues, such as conversion of binary, decimal, hexadecimal numbers, ASCII table	Computer engineering	6
Tax	calculation of taxes, such as income tax	Economy	5

Table 1: Our proposed CS1 Context Taxonomy and Data Set description, with respective non-CS undergraduate course name and Number of items per Context, N

tual paraphrasing. Figure 4 illustrates a paraphrasing process based on a fragment of a statement from the category “Computational”.

Figure 4 shows a new generated sentence with clear semantics for a human reader. Still, generated text sometimes

misses such a clear structure. Nevertheless, our goal here is not to generate new sentences which could be meaningful for learners. Instead, we aim at creating artificial statements, which are not to be presented to humans, but will be used to expand the minority classes, providing variations to the predictive models (see bias-variance trade-off [8]). In other

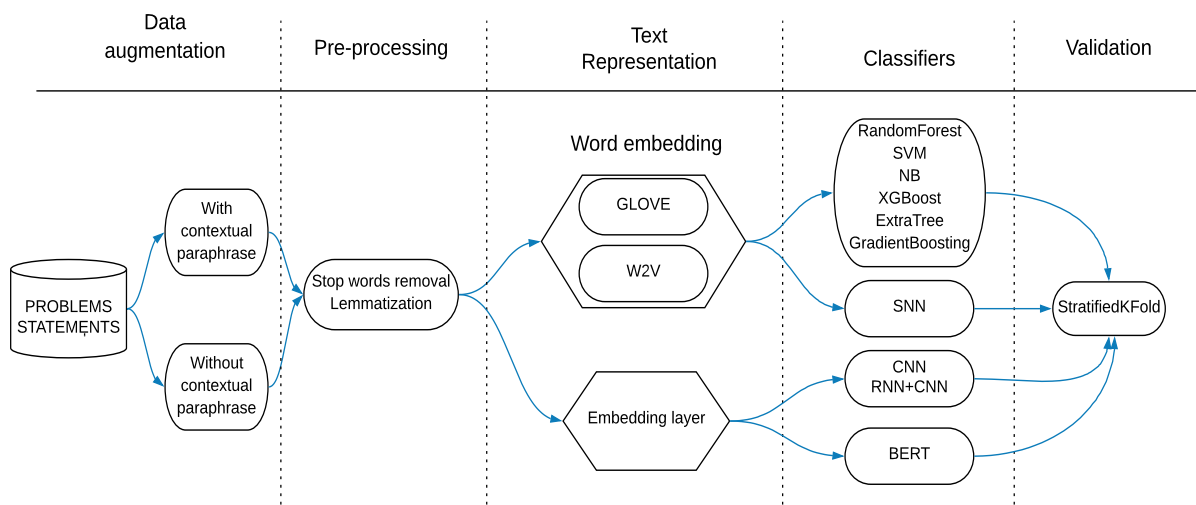

Figure 3: Proposed Automatic Contextualisation Research Methodology Pipeline

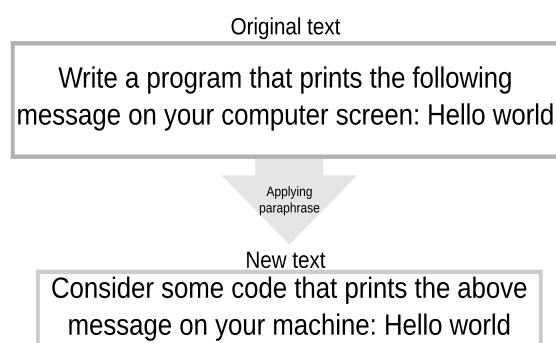

Figure 4: Paraphrasing Example using BERT [6]

words, despite this irregularity in the semantic sense of the statement, it is possible to perceive that the new instance generated belongs to the same class from which it was derived from and, therefore, it may represent a useful addition for the learning algorithm (which is later, as can be seen, confirmed by the results).

Nonetheless, as can be seen, despite the potential of such contextual paraphrasing, the new statements repeat some words from the original and keep almost the same number of tokens, which is a limitation of this method. As such, to prevent overtraining on artificial data (instances created using contextual paraphrases), we have set a limit of, at most, quadrupling the base of minority classes. We established this limit after some empirical experiments. That is, a statement is allowed to generate at most 4 new samples in the training base, as long as the new number of statements is below the number of instances of the majority class. Hence, this process may not render a perfectly balanced training base. To illustrate, imagine that the majority class has 10 questions on the training set, while the minority class has

1 question; with this paraphrasing algorithm, it is possible to extend the minority class for up to 5 questions (4 new samples + original statement).

In this work, experiments were carried out with and without paraphrasing, in order to analyse how the balancing by paraphrasing can influence the results.

5.2 Pre-processing

As we used reliable data (problems statements created directly by instructors/monitors), there was no need in our data processing of performing orthographic corrections, expanding contractions and other common data-cleaning steps. However, all our problem statements were originally in the Portuguese language. As there are many tools available for processing text written in English, we opted to translate our statements first into English, by using the *googleTrans*² library. Subsequently, we proceeded in applying our pipeline processing on the English text obtained, with and without the use of *stop-words* removal and *lemmatization*, using *spacy*³. As a result, we observed empirically that these two techniques were useful for data filtering in our pre-processing step. Next, we show how we further prepare the text for the machine learning algorithms.

5.3 Text Representation

The machine learning algorithms take as input a sequence of text to learn the structure of text, just like a human does. However, we need to convert the data in numerical form. As such, we represent our text data as a sequence of numbers (see Keras Tokenizer function⁴). Moreover, the ML algorithm expects each training instance to have the same length (same number of tokens). Thus we padded with zeros at the end sequences that are shorter than the maximum length

²pypi.org/project/googletrans/

³spacy.io

⁴keras.io/preprocessing/text/

sequence. To do so, we applied the Keras padding module⁵ over the sequences.

In addition, two different state-of-the-art NLP techniques for vector representation of words are used for competing against each other: googleNews-Vectors (W2V)⁶ and Glove [16] word embeddings. Moreover, for the BERT classifier, we used its own layer of word embeddings. Similarly, for the other deep learning models, we used the word embeddings layers as provided by the Keras library⁷. The purpose of this step is to compare the NLP techniques in terms of performance with our data set. Therefore, we created a *process to obtain the best model for automatic categorisation of contexts of programming questions* for our educational context. The process allowed us thus to carry out experiments with advanced Deep Learning methods, and to compare not only those approaches with each other, but also with classical approaches, such as shallow learning models.

5.4 Classifiers

For deep learning models we used: a) Convolutional Neural Networks (CNN) which have a convolutional layer, followed by three dense layers; b) Recurrent Neural Networks (RNN), with a recurring layer using a Long Term and Short term memory (LSTM) followed by three dense layers; c) RNN and CNN (RNN+CNN) stacked with the same configurations as those of the items a and b; d) Sequential Neural Network (SNN) with two dense layers and e) BERT for classification (notice that we used BERT for two purposes: i) perform contextual paraphrasing; ii) multi-classification).

As we are tackling a multi-classification problem, the final layer for each neural network was represented by a softmax layer [13]. For all deep learning models, the configurations used above represent the default recommended ones from the literature [13].

Additionally, we used the following classical, shallow classifiers, with the word embeddings from googleNews-Vectors and Glove: Random Forest Classifier (RFC), Support Vector Machine (SVM), Extremely Randomised Tree Classifier (ETC), Gaussian Naive Bayes (GNB), XGBoost (XGB) and Gradient Boosting Classifier (GBC).

5.5 Validation

To validate the models, we employed the stratified validation with 10 *folds*. This method divides the base into k partitions, using $k - 1$ for training and 1 for testing. After that, the accuracy of the test partition is calculated. This process is repeated k times, until all partitions have been used as a test. Finally, the average of the accuracy obtained in the tests is computed. It is noteworthy that each *fold* was divided proportionally to the number of statements present in each class in the database [13]. We implemented it using the *StratifiedKfold* from scikit-learn. Notice that we performed the data augmentation only on the training sets of each training fold. Thus, there were no paraphrased texts in the test sets.

⁵keras.io/preprocessing/sequence/

⁶code.google.com/archive/p/word2vec/

⁷keras.io/

To evaluate our models, we used the F1-score, as this metric combines precision and recall in an harmonic mean. This is useful because it gives much more weight to low values than a regular mean, which treats all values equally. Moreover, we used the weighted F1-score, which takes into account the proportion of each class.

6. RESULTS AND DISCUSSION

We built a total of 34 predictive models. Figure 5 illustrates all the results obtained by all models applied in this research. From this figure, we can notice that paraphrasing improved the (weighted) *F1-score* in all models. To illustrate this boosting, the model *GLOVE + SVM* achieved a F1-score of 86%, without paraphrasing. Whereas with the paraphrasing, the model achieved 94%, an increase of 8%. To validate that, we performed the McNemar's hypothesis statistical test, which is recommended to compare machine learning models [7]. We compared the models with or without the contextual paraphrasing. As a result, we confirmed that the paraphrasing statistically boosts all models, even after Bonferroni correction ($p - values \ll 0.05/2$). Table 2 shows the classification performance of the models in terms of macro and weighted precision, recall and F1-score. Moreover, this table shows the accuracy of each model.

From a visual inspection of Figure 5, we can argue that the best model found is the BERT classifier with use of the contextual paraphrasing (BERT + PAR), as the model has the highest median and a low standard deviation. Moreover, this model achieved the highest recall, F1-score and accuracy (Table 2). To validate that, we also performed McNemar's test. As a result, we confirmed our previous deduction as *BERT + PAR* statistically outperforms all the other models, even after Bonferroni correction ($p - values \ll 0.05/33$). As such, in Figure 6, we show the performance of this model for each context, as a *heat-map plot*. The rows represent the actual values, while the columns depict the predicted contexts.

Figure 6 illustrates that, in general, our best model is capable of recognising problems from each context with a high recall. Indeed, there are predictions in some classes without miss-classification such as *Computational*, *Sports*, etc. However, we can see some cases where the model made mistakes. For example, the model gets confused between the classes *Production* and *Commercial*. This may have happened because some problem statements could have come from a production context, but with focus on sales, which would be further related to the *Commercial* context. Moreover, there are some problems that are actually from the context *Production*, classified by our best model as *Date and time*. This was an unexpected result for us. After visual inspection, we noticed that some of these problems linked the efficiency of a company to the time-scale (e.g., how long a process took determined its efficiency). This is a possible explanation for such confusions within our model.

Coupled with that, according to Table 1, it is possible to notice that the class *Computational* has only a few statements. Despite this low number of problems in this context, our model is able to recognize this minority class with no errors (100% of precision and recall). Still, the class *Tax* presents the lowest number of problems in our database.

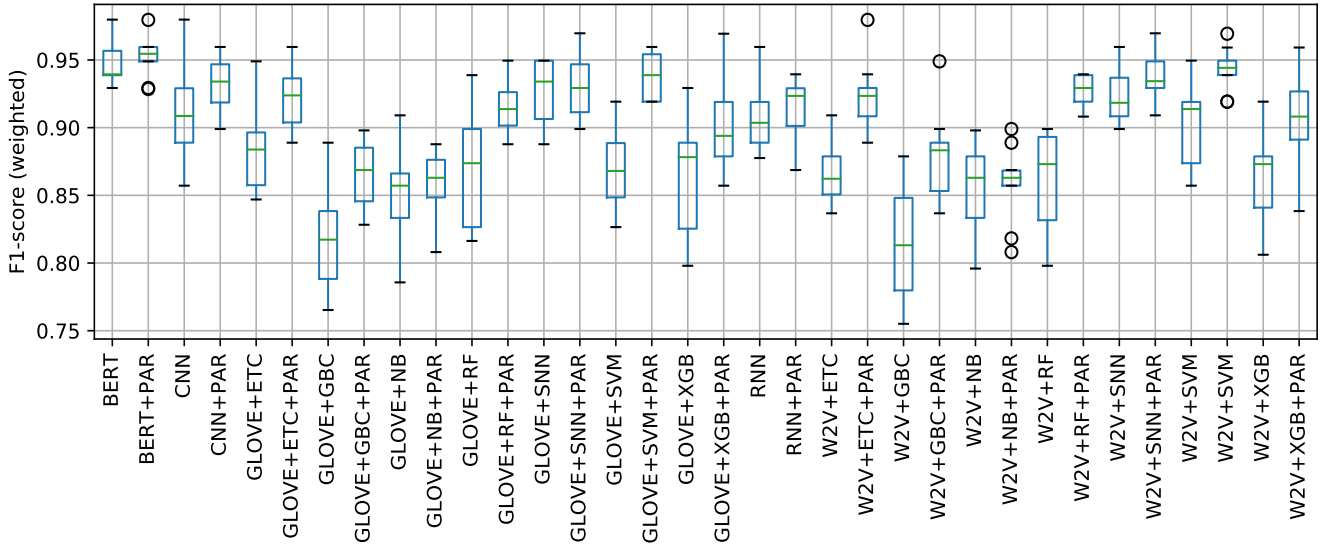

Figure 5: All results (F1-score)

But even so, our model achieved a recall of 80% in this context. Consider that the instances missclassified from the *Tax* context were allocated to *Commercial*, which makes sense, as, in some cases, these two contexts are related.

Although the model achieved a high recall (95%) in the context of *Games*, instances that the model was not able to recognise were spread through multiple contexts (*Commercial*, *Date and time*, *Physics*, *Tax*, and *Mathematical*). The 2% error between *Games* and *Tax* can be explained by statements of games that comprise tariffs, e.g., when buying a certain product within the game. For example, there are statements in our data set that discuss buying products for a character, such as a battle suit. Further, the error of 1% with the class *Commercial* could be due to a reason similar to that of the class *Tax*. To illustrate, within a game, some statements comprise the purchase of products. Regarding the class *Date and time*, an explanation would be statements that address some mission that the character needs to accomplish in a specific time. Regarding the error in the classes *Physics* and *Mathematical*, it may be due to statements in games that contain speed calculation.

Another important analysis to be done occurs in the class *Research*. The model achieved a recall of 94%, whereas 6% of errors occurred in the class *Person*. One possible reason is that surveys are conducted based on a group of people. Also, there are statements in our database that contain research carried out on some characteristics of people, such as age group, education, etc.

Another interesting outcome relates to the following classes: *Banking* and *Commercial*. Note that both presented confusion errors between each other, that is, the class *Commercial* presented wrong predictions in the class *Commercial* and vice-versa. This is justified because both classes deal with statements that involve money.

Furthermore, a similar situation occurs for the classes *Health* and *Population*. Here, errors could be due to statements addressing, e.g., the growth of a virus or bacteria. Thus, results may highlight relations between these contexts.

Another interesting analysis relates to the majority class of our data set, that is, the class *Mathematical*. Note that it was possible to obtain here a 99% recall. Even more importantly, note that few classes have errors in this class, that is, although we are dealing with the majority class, our model can differentiate, with high precision, all classes, against this one. To illustrate, only the following classes had a confusion error with respect to this class: *Games*, *Geography* and *Commercial*. Regarding the error presented in the prediction of the class *Games*, it is an error that could be justified by questions that deal with any type of calculation, given that any form of calculation can be directly related to the mathematical context. For the *Geography* class, the error could be justified, as we have noticed the existence of statements that deal with map scale conversion. Regarding the class *Commercial*, the error could be justified by calculating the price of a certain product.

Nevertheless, we had unexpected outcomes as well. For example, it was arguably to be expected that the *Physics* class presented errors in the *Mathematical* class, given that statements that address a physical contextualisation deal with mathematical calculations. However, this does not happen. Thus, our model clearly differentiates here between even small details present in the statement of each context.

In other words, although there is an error in the classification of some instances in the classes, most of these errors can be easily justified. This may suggest that the statements worked on in this research have multi-contextualisation, that is, a statement can address more than one context. However, what happens in practice is that one context is predominant, and the prediction of our model reflects this. Still, it is

Table 2: Classification performance of the predictive models (Pr: precision; Re: recall; F1: F1-score; Acc: accuracy).

potentially useful to further analyse this problem as a multi-contextual prediction task.

7. LIMITATIONS

One of the major limitations of this paper is related to data set size. Although we have a significant number of problems, in the case of some contexts there is a small number of instances, due to the quantity of classes in our multi-classification problem. To address this limitation, we used cutting-edge NLP techniques to produce new instances on the training set, using contextual paraphrases.

Moreover, our original problem descriptions were in Portuguese and hence, when we translated them to English, this may have introduced some errors from our automatic data processing. However, this was counter-balanced by the availability of the most cutting-edge NLP processing tools for the various steps involved in our pipeline, which were not available for the Portuguese language.

In addition, this research worked with introductory topics to computer programming. It is thus less clear if the methodology applies to more advanced topics of programming. For example, database disciplines may need a different approach. However, the holistic pipeline we propose can guarantee that the right method can outperform the others, thus ensuring area appropriateness.

Another limitation arises from undergraduate courses that do not have programming in their curriculum. Although it is clear that in this research several courses may use programming for some activities, not all of them have programming topics in the curriculum. To illustrate, although our data set presents health issues that can be applied to the medical or nursing courses, unfortunately these undergraduate courses do not have programming topics in their curriculum. This may however change in the future, with the rise of the ubiquitousness of computing, and thus this research may have wider relevance and impact than originally envisioned.

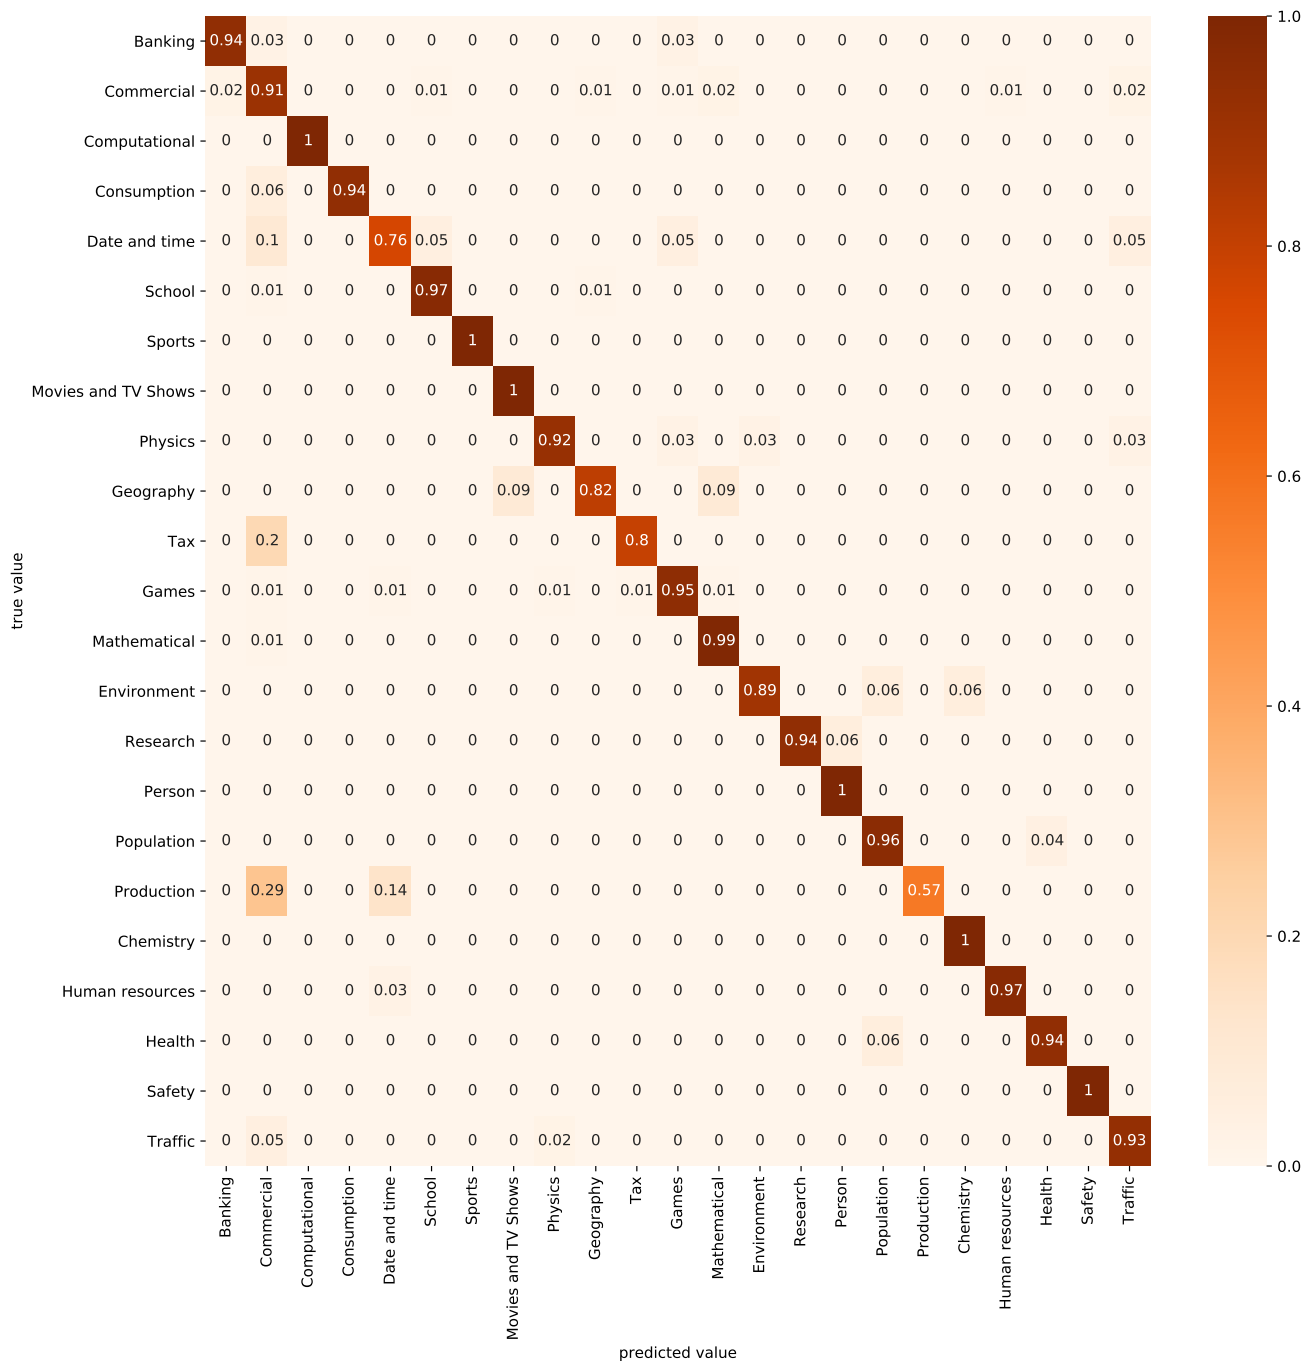

Figure 6: BERT with Paraphrasing

8. CONCLUSION AND FUTURE WORKS

According to the results obtained and illustrated in this research, we can conclude that paraphrasing of the minority classes boosts results, that is, it was able to make predictive models more accurate and with greater recognition capacity, regardless of which NLP was used, that is, Glove, Word2vec, BERT, etc.

In addition, our work was able to achieve a performance with high precision and a high recognition rate for all 23 classes

proposed in this article. That is, our best model, which is based on the BERT technique with paraphrase-balancing, was able to achieve an accuracy of 95.2% with a minimal error rate, which is no more than 4.8%.

With that, the first step to *generate personalised problem lists, according to the context of the undergraduate course*, was taken. We have additionally provided a *new context taxonomy for problems*, as well as a *comprehensive evaluation pipeline methodology for context-based personalisation*

of problem lists.

As future work we intend to further evaluate the effect of the personalised programming problem assignments using our method to detect the subject matter. Thus, we can explore if the performance of the non-CS students will be affected when solving problems related to their courses.

In addition, three new experiments can be performed to analyse the generalisation power of our method. The first is to repeat the procedure on other online judge problem collections, but still at an introductory programming discipline level. The purpose of this experiment is to verify how generalisable our approach is across educational settings different from ours. We believe, nevertheless, that choices such as the programming language used in teaching CS1 will not be a factor that will prevent similar outcomes.

As a second experiment, we would repeat the procedure with more advanced programming topics, to analyse if the method can be applied to these more complex types of topics. For example, disciplines such as data structures may be a research target. Finally, we envision to adapt our pipeline to perform automatic classification of the programming problems in terms of the topics used in the CS1 courses (*Sequential, Composite conditional structures, Chained conditional structures, Repeating structures by condition, Repeating structures by counting, Vectors and Strings and Matrices*). Such a pipeline would be useful for several applications, such as for problem recommendation, automatic annotation, amongst others.

Concluding, we believe that the automatisisation of the classification of statements by contexts is extremely relevant for several reasons, among which we highlight: i) statements which students are already familiar with can help in the process of engagement and learning; ii) students will find it easier to understand the relevance of programming in their professional lives; iii) teachers can use this automatisisation to generate personalised lists, which would facilitate their work, since it would be too much work to select these problems manually, in addition to which it could lead to human error and iv) students could use this automatisisation to select problems to which they are used to, facilitating their process of learning a certain programming topic.

ABSTRACT

In recent years, game-based learning has shown significant promise for creating engaging and effective learning experiences. Developing models that can predict whether students will struggle with mastering certain concepts could guide adaptive support to assist students with mastering those concepts. Game-based learning environments offer significant potential for unobtrusively assessing student learning without interfering with gameplay through stealth assessment. Prior work on stealth assessment has focused on a single machine learning technique such as dynamic Bayesian networks or long short-term memory networks; however, a single modeling technique often does not guarantee the best predictive performance for all concepts of interest. In this paper, we present a hybrid data-driven approach to stealth assessment for predicting students' mastery of concepts through interactions with a game-based learning environment for introductory genetics. Stealth assessment models utilize students' observed gameplay behaviors using challenge- and session-based features to predict students' learning outcomes on identified concepts. We present single-task and multi-task models for predicting students' mastery of concepts and the results suggest that the hybrid stealth assessment framework outperforms individual models and holds significant potential for predicting student competencies.

Keywords

Stealth Assessment, Predictive Student Modeling, Game-based Learning, Multi-Task Learning

1. INTRODUCTION

Recent years have seen growing interest in game-based learning environments because of their potential for creating engaging and effective learning experiences [7, 43]. Researchers have investigated game-based learning environments in a wide array of

domains, including mathematics [13, 40], computational thinking [4, 16], and science [2, 10, 30].

While a common gameplay design adopted by many game-based learning environments is providing students with a fixed sequence of levels with increasingly difficult challenges per concept, game-based learning environments could provide individualized sequences of challenges and just-in-time support, so that students can focus on gameplay at the edge of their knowledge and skills and remain engaged throughout the learning experience [20, 44]. To achieve this goal, game-based learning environments should be equipped with the ability to detect when students are struggling or have gaps in their knowledge and take appropriate action to tailor their learning experience [33]. Presenting in-game challenges adaptively tailored to individual students' knowledge can play a crucial role in supporting mastery learning and promoting engagement while effectively addressing problems with a one-size-fits-all approach.

With recent advances in machine learning, data-driven approaches using students' in-game behaviors have enabled the automatic assessment of students' evolving competence [1, 21] and the modeling of mind wandering [19], wheel spinning [25], and quitting behaviors [12], all of which are associated with negative learning outcomes. A robust modeling of student behaviors can guide students from undertaking a challenge that is beyond their capabilities as well as facilitate their engagement through individualized learning activities tailored to their competencies for knowledge and game-playing skills.

There is now a sizable literature on stealth assessment in game-based learning [34]. Stealth assessment robustly measures student learning without disrupting engagement by embedding unobtrusive assessments within game mechanics, offering real-time non-disruptive assessment [35]. Building on evidence-centered design (ECD) [24], which provides a systematic approach to developing knowledge assessments, stealth assessment examines student interaction data (i.e., evidence model) with in-game challenges (i.e., task model) to provide real-time behind-the-scenes measurement of students' learning processes and outcomes (i.e., competency model) [22, 36]. Specifically, students' learning is inferred by analyzing low-level sequences of observed problem-solving behaviors that manifest competencies for knowledge and skills without conducting explicit formative assessments. Inferences made by stealth assessment models can inform effective

Nathan Henderson, Vikram Kumara, Wookhee Min, Bradford Mott, Ziwei Wu, Danielle Boulden, Trudi Lord, Frieda Reichsman, Chad Dorsey, Eric Wiebe and James Lester "Enhancing Student Competency Models for Game-Based Learning with a Hybrid Stealth Assessment Framework" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 92 - 103

scaffolding strategies (e.g., adaptive challenge selection, tailored problem-solving support) for individual learners in a timely and contextually appropriate manner [29, 36]. It can also guide teachers to potential pedagogical adaptations or support integration with additional curricular activities, which are core components of distributed and integrated scaffolding [26, 28, 39].

In this work, we investigate stealth assessment with *Geniventure*, a game-based learning environment for introductory high school genetics learning. We present modeling approaches including single-task and multi-task random forest and recurrent neural network-based regression models for predicting students' competencies, whose labels were derived from students' post-test scores on genetics-focused concepts. In contrast to much previous work on stealth assessment that used a single machine learning technique, we present a hybrid stealth assessment framework that effectively leverages predictive capacities of all the explored modeling approaches. We compare the models' fitness to the data to gain insight into which combinations of models perform optimally across all the concepts, as well as which models are effective for individual concepts. The hybrid stealth assessment framework outperforms individual computational techniques with respect to predictive performance for student concept-level competencies.

2. RELATED WORK

Intelligent game-based learning environments simultaneously leverage capabilities of digital games to motivate students' learning through engaging narratives, virtual environments and intelligent tutoring systems (ITSs) to foster students' learning through adaptive scaffolding and context-sensitive feedback [15]. These environments facilitate learning through individualized challenges, narratives, feedback, and problem-solving support [30, 35, 42]. Students' fine-grained, sequential game trace data has been used in a wide range of student modeling tasks such as inferring the level of competency [22, 35], predicting affective states [3, 31], and recognizing students' learning goals [23]. In comparison to single-task learning investigated in much of previous student modeling work, recent years have seen a growing interest in the use of multi-task learning, a regularization method that exploits commonalities and differences across related tasks for improved generalizability. Multi-task learning has been examined for various student modeling tasks such as predicting student competencies in programming in a massive open online course (MOOC) [27] and modeling student performance in a game-based learning environment for middle-grade microbiology education [9], which demonstrated improved predictive performance relative to the single-task modeling approach. Similarly, Chaudhry et al. used multi-task modeling with both hint usage and knowledge tracing to induce models of students using online tutoring systems [5].

Stealth assessment is methodologically grounded in evidence-centered design (ECD), which was proposed to construct educational assessments in terms of evidentiary arguments [24]. ECD features task, evidence, and competency models to conduct probabilistic reasoning about knowledge, skills, and abilities of students utilizing evidence captured from interactions with learning tasks. Stealth assessment conducts real-time processing of data derived from these three ECD models that informs intelligent, adaptive game-based learning environments through devising robust evidence and competency models as well as creating task models that effectively develop the competencies [20]. While human expert-designed Bayesian networks have been examined as the core computational method for both competency and evidence

models for stealth assessment [37], another body of work has investigated an assessment pipeline that does not require costly domain knowledge engineering. Falakmasir et al. investigate the use of hidden Markov models (HMMs) to model student proficiency within educational games [8]. The log-likelihoods are approximated by the HMMs using sequential gameplay data, with the difference between the likelihoods serving as the independent variable for post-test prediction models. The authors of this work use linear regression to predict the student's post-test scores. There has also been growing interest in deep neural network architectures due to their capability to learn salient features from low-level, sequential data captured from interactions with task models [1, 20]. Long short-term memory network-based stealth assessment models have demonstrated significant promise by outperforming competitive baselines with respect to predictive performance of inferring students' competencies, while effectively eliminating the need to manually craft evidence rules and evidence models. In contrast to much of previous research, our work presents a hybrid stealth assessment framework that utilizes a suite of competency models to optimally harness distinguished predictive capacity yielded by a range of single-task and multi-task stealth assessment models.

3. DATASET

3.1 *Geniventure* Learning Environment

To evaluate the performance of our hybrid stealth assessment framework, we use gameplay interaction log data collected from students engaged with a game-based learning environment for introductory genetics for middle school and high school students (students ages 11-18 years), *Geniventure*. The design of the game is guided by core genetics-based concepts that align with the Next Generation Science Standards [38]. *Geniventure* engages students in exploring heredity, dominant and recessive traits, and the protein-to-trait relationship by breeding and studying drakes, a model species for dragons [18].

The game consists of 60 increasingly difficult puzzle-like challenges across 6 levels (Figure 1). Each of the challenges is part of a "mission", with each level containing multiple missions. The genetics concepts that the game addresses are presented through a variety of challenge types. While the game was designed to be played through in a linear fashion, students have the freedom to attempt challenges at any level and are allowed to quit a challenge at any time.

In the first half of the game, students are asked to change the drake's genotype to match a target phenotype (Figure 1, Level 1). To successfully complete these problem-solving challenges, students must understand several genetic concepts and be able to infer the phenotype of their drake from its genotype. Once students feel they have the correct genotype, they click the "Check" or "Hatch" button to submit their answer. If the drake they create matches the target drake, the challenge is successfully completed. Otherwise, the game provides the student with three progressively more directed levels of hints, as well as a visual cue, and allows them to continue to make further changes to the alleles until they quit or successfully complete the challenge. This model of counting moves and giving feedback in the form of hints is carried through the subsequent levels of the game, even though the challenge types vary. Other challenges instruct the user to match a phenotype to a given genotype, following a reversed procedure from Level 1 (Figure 1, Level 2), and also introduce scale color and other additional complexities to the challenges (Figure 1, Level 3).

Figure 1. Example challenges in *Geniventure* for the six gameplay levels.

The latter half of the game introduces more difficult concepts such as breeding and inheritance. Through several scaffolded challenges, students breed parent drakes with the goal of matching target offspring (Figure 1, Level 4). The tasks grow increasingly complex as students progress through this level, eventually culminating in a challenge requiring students to breed two parents to produce offspring that match a given drake. Students are also introduced to test cross, a genetic method for determining the genotype of one organism by crossing it with a fully recessive organism (Figure 1, Level 5). Finally, the last level introduces traits with more complex inheritance patterns, such as X-linked and polyallelic traits (Figure 1, Level 6). This level contains challenges illustrating concepts from all of the preceding levels such as allele target match, egg drop, meiosis, breeding, and test cross.

As previously mentioned, students can validate their work at any time and are provided with system-generated hints based on their perceived understanding of the genetics concepts if necessary. Hint usage, as well as time spent on challenges, and the students' success rate during their respective gameplay sessions, serves as the foundation for the features used to train the competency models.

3.2 Data Collection

The dataset was collected from 462 students from seven high schools and one middle school located in the Middle to Northern Atlantic coast of the United States. This data was collected during a teacher-led classroom implementation of *Geniventure* where students played the game during class over the course of several days. During gameplay, students' gameplay trajectory and their detailed in-game actions were recorded as trace data logs. Before playing the game, students took a pre-test consisting of 28 questions related to the genetic concepts covered in the game. Once gameplay concluded, students took a post-test which was identical to the pre-test (Figure 2). This assessment was aligned to the ECD competency model of the game and previously validated through two rounds of expert review and cognitive interviews with students. In administration, it demonstrated an internal consistency reliability of $\alpha = 0.873$. Both the pre-test and post-test were online surveys

accessible through the same online portal as the game. 38 students were removed due to the partial or missing pre/post test data. 108 students were removed due to missing trace data, resulting in a dataset containing trace data from 316 students. Results from a paired t-test on students' knowledge pre-test ($M = 14.41$, $SD = 5.826$) and post-test ($M = 19.33$, $SD = 6.131$) revealed a significant improvement from pre-test to post-test ($t(315) = 14.663$, $p < 0.01$, Cohen's $d = 0.823$). A majority of the students attempted between 50 and 150 challenges. The fewest number of challenges attempted by a student was 5, which serves as the basis for the sequence length of the subsampling window used to generate the sequential data for the competency models. The most challenges attempted by a student during the duration of the study is 248. To further illustrate the distribution of the number of challenges attempted per student, a histogram of the students' gameplay trajectories is shown in Figure 3.

4. ECD FOR STEALTH ASSESSMENT

Evidence-centered design (ECD) is a systematic approach for designing and developing reliable knowledge assessments in terms of evidentiary arguments [24]. When utilized to identify and analyze user behavior in online learning environments, it serves as the basis of stealth assessment in game-based learning environments [34]. While historically ECD has been utilized in the development of summative assessments, recent years have seen its application in the design of formative stealth assessment models for game-based learning environments [20, 34]. Assessment results inferred by stealth assessment models can be utilized to support student learning through adaptive scaffolding within the learning environment and also inform teachers about student learning trajectories through a teacher dashboard. As noted above, stealth assessment is grounded in three core ECD models. These three models were applied to the current study using *Geniventure* as follows:

- **Task Model:** This model defines the activities, or tasks, that students undertake as part of their learning. In the *Geniventure* learning environment, the task model consisted of 60 challenges across six game levels that students undertake.

These tasks focus on genetics concepts such as heredity, dominance/recessive, and the protein-to-trait relationship.

- **Evidence Model:** The evidence model takes as input low-level action sequences students produce while interacting with the game-based learning environment. Game-based learner behaviors are linked to targeted concepts to generate machine-interpretable evidence that can be directly utilized with the modeling techniques presented here. That is, a probabilistic model is constructed from analysis of a series of actions related to mastery (or not) of a particular concept. The evidence model informs the competency model in order to update its belief of students' competencies as they interact with the tasks.
- **Competency Model:** Mastery of 16 concepts (Table 1) are dynamically estimated by the competency model with respect to students' genetics knowledge. The concepts were derived from expert review of classroom learning goals and state science standards. The ground truth for their summative competencies are acquired from students' post-test scores on an explicit content knowledge assessment. The competency model is aligned to the summative post-test through the same set of ECD-derived concepts in Table 1.

In training the stealth assessment models, we extract competency scores based on correctness of students' individual responses to items on a post-test knowledge assessment (Figure 2). Competencies for a single concept in our competency model can be

Here are two whiptail parents. Remember, straight wings (W) are dominant to curly wings (w), fire breathing (F) is dominant to non-fire breathing (f) and dark gray (G) is dominant to light gray (g).

Dad
(Ww, Ff, gg)

Mom
(Ww, FF, Gg)

Question #8

Which combination of gametes can these parents produce that would combine to create a curly-winged, fire breathing, dark gray whiptail baby?

☐ Dad (w,F,g) and Mom (w,f,g)
☐ Dad (W,F,G) and Mom (w,f,g)
☐ Dad (w,F,g) and Mom (W,f,g)
☐ Dad (w,f,g) and Mom (w,F,G)

Question #9

Which combination of gametes can these parents produce that would combine to create a straight-winged, fire-breathing, light gray whiptail baby?

☐ Dad (W,f,g) and Mom (W,f,g)
☐ Dad (W,f,g) and Mom (w,F,g)
☐ Dad (w,F,g) and Mom (W,f,G)
☐ Dad (w,f,g) and Mom (w,F,G)

Figure 2. Example post-test question.

Figure 3. Histogram of students' gameplay trajectories.

evaluated in as few as one or as many as six items on the post-test survey since an assessment item can map to either one or two concepts. Item 28 is an open-ended question that can be answered in many unique ways, so we omit it from our competency score calculations. The mappings from each concept to individual survey questions can be found in Table 1.

Each of the test items is recorded in a binary format, with 1 if the student answered the item correctly and 0 if the item is answered incorrectly. To calculate the competency score for each concept, the total number of correctly answered items was divided by the total number of items for that concept, resulting in a score between 0 and 1. These scores serve as the target labels for our regression models.

5. METHODOLOGY

We evaluate two different approaches to the student competence modeling: single-task and multi-task. The single-task approach involves training an individual model for every concept, with each model only predicting a single competency score. This architecture allows for the model to focus exclusively on modeling trends and correlations between the students' gameplay features and a single competency and does not take into account any interrelationships between the gameplay and multiple concepts. The multi-task approach requires a single model trained to approximate all competency scores using a single 16-unit vector. This approach is advantageous as it is capable of modeling complex, non-linear relationships between the various concept-level competencies that exist within the gameplay data. Multi-task modeling has seen an increase in usage due to its reduced number of parameters to be estimated, as well as the computational time required to train a model for each dependent variable, compared to the single-task modeling technique. Multi-task models' capability to robustly model inherent relationships between multiple dependent variables using a shared input vector space makes this modeling technique ideal for stealth assessment frameworks, as well as circumstances where a large amount of training data may not be readily available [9].

We evaluate these two approaches using two different feature representations of the students' gameplay data: static and sequential representations. The static representation of the data involves producing a single feature vector representative of each student's overall interaction with the *Geniventure* learning environment, resulting in a single dataset of 316 total data samples. The sequential representation is used to model subsequences extracted from individual challenge-level interactions across each student's gameplay trajectory, retaining temporal information based on the order the challenges were completed. This sequence sub-sampling approach results in a single dataset of 29,977 total data samples.

5.1 Interaction Data

Gameplay interactions with the *Geniventure* game environment were recorded in a timestamped log file for each student. The trace data log is a raw event stream in JSON format which records fine-grained information about students' actions in the game, such as a navigated challenge, changed allele, submitted answer, and received hints from the system. The types of actions vary among challenges because of the differences in the challenge settings. To eliminate the influence of the differences in challenges, we defined 10 generic measurements across different challenges that describe contextual information about the challenge itself. The remaining features summarize students' performance and actions within an individual challenge. For each student, we generated his/her

gameplay trajectory across each individual challenge attempted. The length of the challenge level trajectories varied from 5 to 248 ($M = 95.86$, $SD = 33.63$). Each of the features forms the basis for the static and sequential data.

Table 1. Competency model concepts

Concept Number	Concept Description	Number of Questions
C1	Only one dominant allele is needed to produce the dominant trait.	3
C2	Two recessive alleles are needed to produce a recessive trait.	2
C3	Create or select parental gametes to create an individual offspring with a specific phenotype.	4
C4	Set parental genotypes to produce a specific pattern of offspring.	6
C5	Use patterns in the phenotypes of a group of offspring to predict the genotype of the parents.	5
C6	For some traits primarily influenced by a single gene, both alleles will have some effect, with neither being completely dominant.	2
C7	Breed with a recessive animal to determine an unknown genotype (testcross).	2
C8	Different versions of a gene correspond to (lead to the construction of) different versions of a specific protein.	2
C9	Proteins do work or have jobs to do in cells.	1
C10	Proteins are nanomachines; different proteins do different jobs.	1
C11	The function of a protein is determined by its shape.	1
C12	Different versions of a specific protein have different structures and may also have different functions.	1
C13	Some traits have multiple alleles, which can form a ranked series in terms of dominance.	2
C14	Genes on the X chromosome are referred to as X-linked. Males receive only one copy of the X chromosome and pass on their X only to their daughters.	1
C15	Working from the phenotype, determine possible genotypes for an organism.	2
C16	Use a genotype to predict the phenotype for an organism.	2

The features representing each challenge undertaken by a student are: (1) Pre-test score, (2) level of challenge, (3) mission number of challenge, (4) challenge number, (5) total time spent on challenge,

(6) number of movements made during challenge, (7) number of hints encountered during challenge, (8) number of correct movements made during challenge, (9) number of wrong movements made during challenge, and (10) student's completion status of challenge (0: incomplete, 1: complete with wrong answer, 2: complete with correct answer).

5.2 Static Competency Models

We evaluate five different regression models to determine their capabilities to predict students' competency levels for each concept. The features selected for the static competency models summarize the whole gameplay of each student across all challenges and levels. Using the challenge-level features noted above, the summative student-level features generated for the static models are (1) average time spent per challenge, (2) total time spent playing challenges, (3) fraction of challenges failed, (4) fraction of challenges succeeded, (5) fraction of challenges abandoned, (6) fraction of incorrect movements, (7) fraction of correct movements, (8) total hints received, (9) number of hints per level, (10) hint count per challenge, and (11) number of levels played.

We evaluate two variations of static modeling techniques: single-task and multi-task. Single-task models predict each target concept score as an independent regression problem. The data set and features used in each model are identical, but the target variable is a single competency score for each model. Multi-task models approximate all target variables in a single model. However, not all of the static, single-task models can effectively translate to a multi-task learning environment. Using single-task learning, we aim to discover the best model for each target variable independently while multi-task models perform better when there are underlying dependencies between the various competencies and a student's gameplay features.

5.2.1 Single-Task Models

We evaluate three single-task models. Elastic Net is a linear regression model that utilizes both L1 and L2 regularizations. The hyperparameter tuning of Elastic-Net was performed on the L1 and L2 regularization coefficients (alpha, L1 ratio). Gradient-Boosted Regression (GBR) is a decision tree-based modeling approach that builds an ensemble of weak predictors to approximate the target variable. The model is built in an iterative fashion where each subsequent stage improves on the model created in the previous stage. The hyperparameter tuning for the GBR model was based on fine-tuning the maximum depth of each tree in the model and the total number of estimators added to the model. We also evaluate a Random Forest regressor, another type of ensemble learning method using a 'forest' of decision trees. Each tree is randomly assigned insensitivity to different features in the training data (i.e., feature bagging). This approach allows for larger model ensembles while avoiding overfitting. The hyperparameter tuning for Random Forest was performed on the maximum depth of each tree and the total number of trees in the forest. While both Random Forest and Gradient Boosted Trees are decision tree-based ensemble learners, a notable difference between these two models is how the trees are added to the ensemble. Within Random Forest models, trees are added independently while in GBR models, trees are added incrementally to compensate for the shortcomings of the previous iteration of models. For the single-task approach, we use a single model for each competency score. We keep the regression model type consistent across all competencies and the hyperparameter values consistent across models.

5.2.2 Multi-Task Models

Due to constraints in models, only certain types of algorithms support multi-task modeling. In this work, two types of multi-task regression models are tested: the multi-task version of Elastic Net and the multi-task version of Random Forest. The multi-task version of Elastic Net adds the constraint that the selected features in the model are the same for all the tasks. The Random Forest regressor is one of the few models that does not require any special modification to support multi-task learning due to the trees in the regressor being built on different subsamples of the dataset.

Each of the static models was implemented using the scikit-learn library in Python. The data set (316 samples) is divided randomly into an 80/20 split with 20% serving as a held-out test set to evaluate the models. The 80% split is used for training the models, with five-fold cross-validation being applied to determine the best model. The training and test splits remain consistent across all investigated models and configurations (e.g., static vs. sequential, single-task vs. multi-task) to ensure a fair comparison between models, as well as the five-fold cross-validation splits. The final hyperparameter values as a result of the cross-validation on the training data are shown in Table 2.

Table 2. Static model hyperparameters

Regression Model	Task Type	Hyperparameters
Elastic Net	Single-Task	alpha = 0.05 L1 Ratio = 0.9
Gradient Boosted Regression	Single-Task	Max Tree Depth = 2 Number of Trees = 20
Random Forest	Single-Task	Max Tree Depth = 3 Number of Trees = 250
Elastic Net	Multi-Task	alpha = 0.2 L1 Ratio = 0.9
Random Forest Regression	Multi-Task	Max Tree Depth = 2, Number of Trees = 200

5.3 Sequential Competency Models

We explore four different types of deep learning-based models to model sequential representations of each student’s gameplay information across attempted challenges. Here, the motivation is to determine whether providing sequential context for each of the student’s problem-solving behaviors induces higher performance when modeling the competencies. To provide further sequential information to each of the models, we generate additional temporal features averaged across all challenges completed up to the current challenge attempted by the user: (1) average time per challenge, (2) average movements per challenge, (3) average correct movements per challenge, (4) average incorrect movements per challenge, (5) average hint count per challenge, (6) average unsubmitted challenges, (7) average failed challenges, and (8) average successful challenges.

We use these features in addition to the 10 static challenge-level features described in Section 5.1 to provide a total of 18 features to each of the sequential models. The models used for both the single-task and multi-task sequential models are variants of recurrent neural networks including Long Short-Term Memory recurrent neural networks (LSTMs) [11] and Gated Recurrent Units (GRUs) [6], due to their capability to model both single-task and multi-task data. LSTMs utilize a sequence of memory blocks that each contain

an input gate, forget gate, and an output gate. The forget gate determines whether the previous memory block’s gradient is retained or discarded, thus allowing the LSTM to model long-term dependencies across temporal sequences, while the input and output gates modulate the input and output vectors, respectively. GRUs are mechanisms that provide the same “forgetting” functionality as LSTMs but contain fewer hyperparameters, utilizing an update gate and a reset gate. This allows GRUs to be more computationally efficient and sometimes more effective on less training data than LSTMs.

In addition to standard LSTMs, we evaluate bidirectional LSTMs (Bi-LSTMs) [32] as well as LSTMs implementing a self-attention mechanism (SA-LSTMs) [41]. Bidirectional LSTMs are a variation of LSTMs that contain two input layers on opposing sides of the hidden layer, allowing the model to retain temporal information based on the past and the future of the input sequence, as opposed to only the past. A self-attention LSTM provides additional temporal context beyond contiguous feature vectors by utilizing a weighted sum of hidden representations of the entire sequence.

Adopting the same manner used in training the static competency models, each model is optimized using 5-fold cross validation, where the data splits are consistent across both static and sequential models to ensure a fair comparison, and then evaluated with the held-out test set. The hyperparameters are tuned using an iterative grid search, and each model was trained for 200 epochs. The subsequences used to train each sequential model were sampled across the challenges completed by each student using a sequence length of 10, and a sampling stride of 1. We use front padding in each sequence during the subsampling process to allow the models to fit during the beginning of each sequence. The concept-level prediction made for each student was calculated by taking the average competency prediction value across an entire sequence. The sequential data modeling pipeline was implemented using Python, and the deep learning models were implemented using the Keras library with the TensorFlow backend. The hyperparameter tuning was performed across the number of hidden units in each model’s hidden layer, as well as the dropout rate in the hidden layer [9]. The final hyperparameter values as a result of the cross-validation on the training data are shown in Table 3.

5.3.1 Single-Task Models

To evaluate the single-task sequential modeling approach, we train 16 different independent models, with each model approximating a single competency score based on the gameplay features described in Sections 5.1 and 5.3. Using the cross-validation performance on the training data, we selected the optimal configuration for each model type based on the highest performance in terms of the average R^2 value across all competency scores.

5.3.2 Multi-Task Models

Because of the architecture of the sequential deep learning models, each single-task model type is also able to perform as a multi-task model, with the only change occurring within the output layer, as the number of output units is expanded to contain an individual output node for each concept, instead of a single concept. This allows a single model to simultaneously infer student competencies across all concepts. Similar to the single-task models, the optimal model configurations were selected based on the average R^2 score across all concepts.

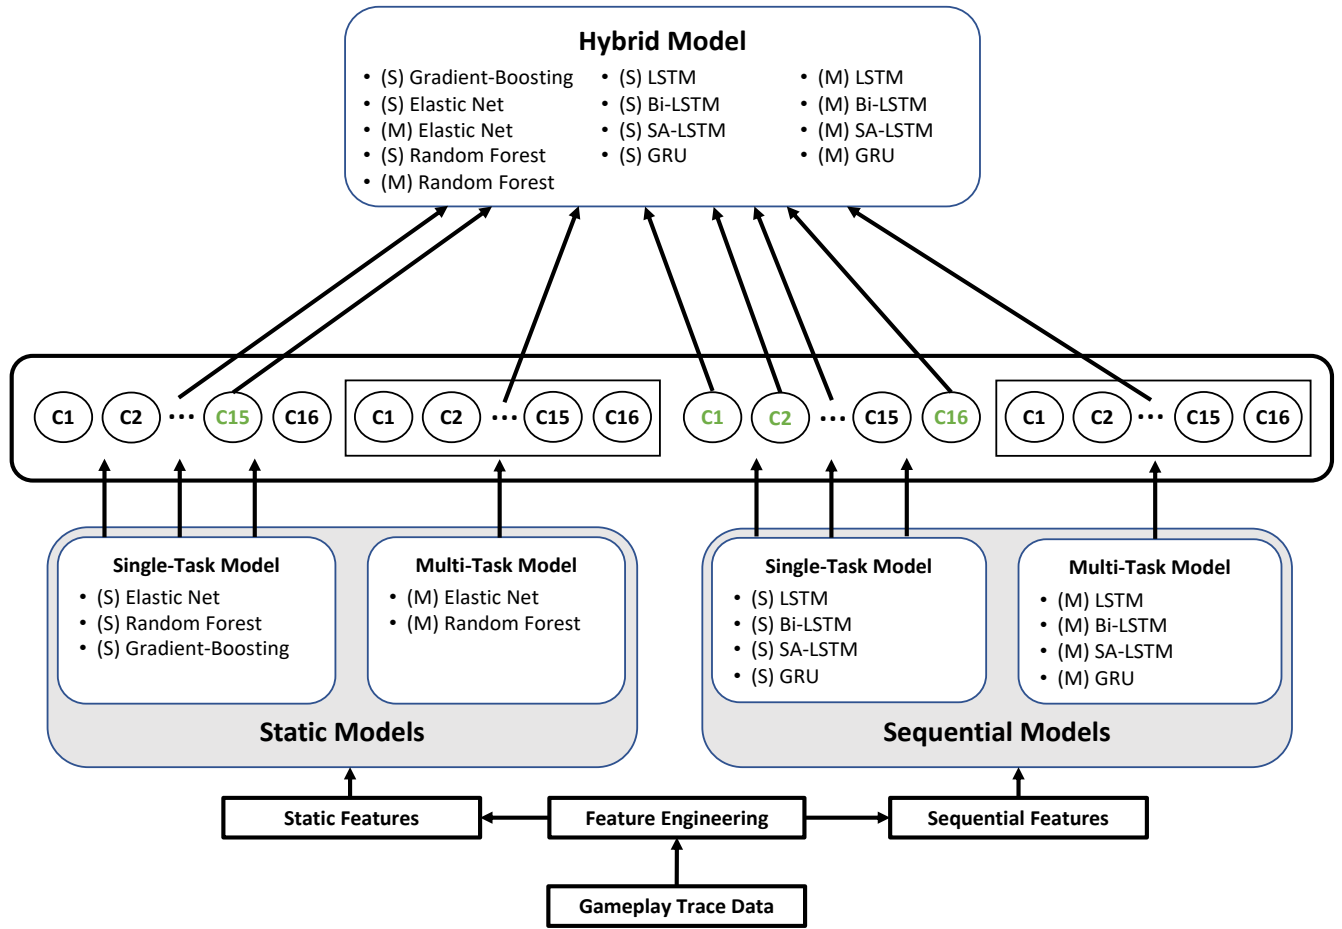

Figure 4. Hybrid, static, and sequential stealth assessment models.

We hypothesize that the optimal modeling techniques will vary due to the different complex characteristics that underlie each concept and the varying fitness of ECD models to these characteristics. Therefore, we propose the use of a hybrid framework that contains a combination of the various single-task and multi-task models that are both static and sequential. A visualization of the proposed hybrid stealth assessment framework comprised of the optimal models (highlighted in green text) is shown in Figure 4 above.

The rationale behind the use of a hybrid stealth assessment framework is that student competencies can vary widely with regards to each concept’s correlation to specific questions in post-test scoring methods, as well as each concept’s correlation to specific gameplay features or levels. By implementing both static and sequential variations of single-task and multi-task models, the long-term and short-term tendencies within each student’s gameplay is explored on a challenge and a student level. Additionally, the relationships between the individual competencies are modeled independently in the single-task approach, indicating whether certain concepts have no interweaving tendencies with other concepts within the gameplay. By utilizing a mixture of both single-task and multi-task models in this framework, multi-task models are only fit where underlying relationships exist between concepts, and concepts that have no underlying relationships with other concepts are optimally modeled by the single-task approach. The same concept applies to the sequential and static modeling: only concepts that have informative temporal trends across a student’s challenge-level gameplay data

are modeled by the sequential models. All other concepts are modeled by the static models utilizing only student-level data.

Table 3. Sequential model hyperparameters

Regression Model	Task Type	Hyperparameters
LSTM	Single-Task	Hidden units = 80 Dropout rate = 0.33
Bi-directional LSTM	Single-Task	Hidden units = 20 Dropout rate = 0.33
GRU	Single-Task	Hidden units = 80 Dropout rate = 0.5
Self-attention LSTM	Single-Task	Hidden units = 60 Dropout rate = 0.33
LSTM	Multi-Task	Hidden units = 100 Dropout rate = 0.5
Bi-directional LSTM	Multi-Task	Hidden units = 60 Dropout rate = 0.33
GRU	Multi-Task	Hidden units = 40 Dropout rate = 0.33
Self-attention LSTM	Multi-Task	Hidden units = 80 Dropout rate = 0.5

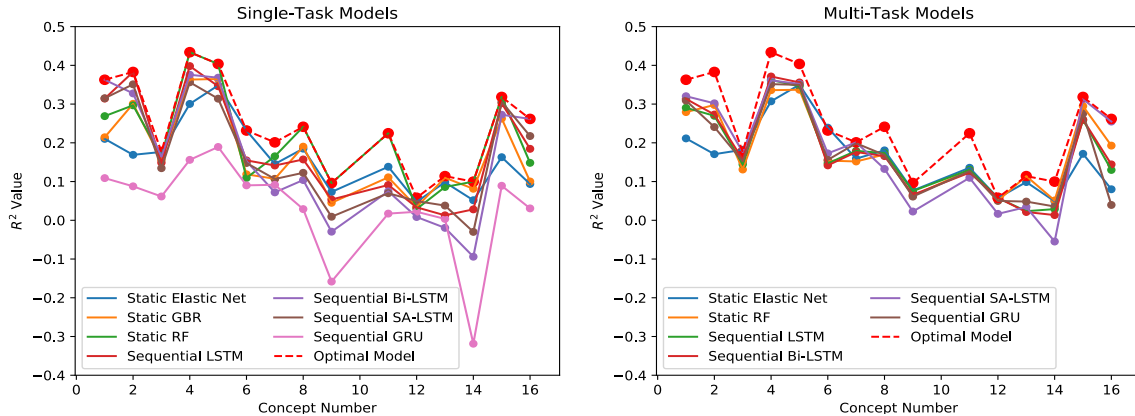

Figure 5. Performance of single-task and multi-task models compared to hybrid model performance.

6. RESULTS AND DISCUSSION

We report the results of the single-task models (Table 4) and the multi-task models (Table 5) for each concept in terms of R^2 . The highest R^2 value produced for each individual concept is presented in Table 6, as this represents the performance of our proposed hybrid framework across all concepts. Figure 5 shows the performance of single-task and multi-task models compared to the performance of the optimal hybrid model (Left: comparison to single-task models, Right: comparison to multi-task models). The results are obtained based on each model's performance on the held-out test set after being trained on the entirety of the training set. As noted above, the cross-validation splits applied to the training set were performed on a student level to prevent data

leakage and were consistently applied to the set of machine learning techniques for a fair comparison across different models. For this work, Concept 10 was omitted because every student that took the post-test survey answered the question correctly, resulting in a dependent variable with zero variance, thus having no impact on the evaluation of our respective models.

The best performing model in terms of average R^2 value across all concepts was the single-task Random Forest; however, it was only the optimal model for 7 out of the 15 total concepts. The single-task bidirectional long short-term memory network performed the highest for two concepts, as well as the multi-task Elastic Net. The single-task LSTM and the multi-task Random Forest (RF), Bi-LSTM, and self-attention LSTM were optimal models for one concept each. The Gradient Boosted Regression (GBR), single-task

Gated Recurrent Unit, and single-task SA-LSTM performed relatively poorly and were not the highest performing competency models for any of the concepts. The multi-task models were the most effective approach for five of the 15 concepts, while single-task models were most effective for the other 10 concepts.

Across both single-task and multi-task models, the GRU was the lowest-performing model, achieving an average R^2 value of 0.102 across all concepts. The results that variants of LSTMs (e.g., standard LSTMs, SA-LSTMs, Bi-LSTMs) achieved the highest R^2 score in predicting student competencies on at least one concept demonstrate that there exist complex, sequential patterns within the students' gameplay data, which were effectively modeled by the LSTMs' three gating units, but not by the two gating units enabled in GRUs. The SA-LSTMs, Bi-LSTMs, and standard LSTM models all returned relatively equal performances across the single-task and multi-task data, with average R^2 values of 0.174, 0.168, and 0.179, respectively. It appears that although the Bi-LSTM and SA-LSTM capture various extra temporal contextual patterns not inherently captured by the standard LSTM, this information is not globally beneficial to all the competency models, explaining why neither model outperforms the standard LSTM on average. However, this result might also be attributed to the fact that the sequential data was only generated from 316 students, which may not be enough information for any of the more complex, sequential models utilizing a higher number of trainable parameters, to truly detect informative underlying temporal patterns.

Selecting the single-task RF as the model for all concepts based on its average performance across all the concepts results in a mean R^2 value of 0.206. However, as illustrated in Table 6, by using our proposed hybrid system approach and selecting the optimal model for each individual concept, we can obtain a performance of 0.241, which is a 17.0% improvement compared to a homogenous framework typically used within stealth assessment. Our observation that the use of multiple models in the hybrid stealth assessment framework would induce higher performance than using a single model can be explained by the fact that static, sequential, single-task, and multi-task models were all selected as an optimal model at least once.

Additionally, it should be noted that when considering only the concepts that mapped to multiple questions (i.e. 1-8, 13, 15-16), the deep-learning based sequential models produced a higher and more consistent performance (0.224 for single-task, 0.222 for multi-task) than the static models (0.214 for single-task, 0.210 for multi-task) on average. The multi-task SA-LSTM and the single-task RF both achieved the optimal performance across the multi-question concepts, with an average R^2 value of 0.239. Random Forest may also perform relatively well as a competence model because it uses an ensemble approach, making it more robust against overfitting.

One correlation that was noted is that the single-task models were the best technique for 75% (3 out of 4) of the concepts that had only one corresponding question in the post-test. This can potentially be attributed to the fact that each of the single-task models only models a single concept, without taking into account any of the linear and non-linear relationships that might exist between the gameplay features and the different competencies for a single student. Concepts that correspond to only a single question possibly contain a less complex relationship between the competency scores and the gameplay features, meaning that a single-task model is sufficient for that modeling task without simultaneously modeling any context related to competencies for other concepts, which can have a detrimental impact to the predictive tasks. In addition, each of the three optimal models for the single-question concepts were trained

using static feature representations, suggesting that the student-level features were the most informative to our model, and the temporal information did not yield greater predictive performance for the student competency models.

However, we also observe that the single-task models were also frequently the highest-performing models for the multi-question concepts. Seven out of the 11 concepts that were represented by multiple post-test questions were optimally modeled using a single-task model, either using static or sequential representations. Out of these 7 highest-performing models, 4 of them used static input representations. In a similar manner to the single-task models mentioned previously, this implies that student-level features were informative for a subset of the multi-question concepts, while the temporal context provided within the sequence modeling tasks was still beneficial to predicting students' individual competencies for the three other concepts.

Overall, the majority of optimal classifiers across the single-question and multi-question concepts were single-task, static representations, as these account for 7 out of the 15 total concepts we evaluated. We then analyze the remaining models to investigate if there are any correlations between the concepts and the optimal models. The competency models for Concepts 1 and 2 were both modeled using sequential single-task models, two concepts that correspond to five combined post-test questions. Concept 1 deals with generating dominant traits using alleles, while Concept 2 deals with a similar task generating recessive traits using alleles. The similarity in these two concepts may be a possible reason that the highest predictive performance was achieved by the same modeling approach. The highest R^2 values (0.434 and 0.404) occurred in Concepts 4 and 5, which are the two concepts that correspond to 6 and 5 post-test questions, respectively. The correlation between the higher performance in these two RF-based competency models can be explained by the fact that ensemble models leveraging more single-task models contribute to improvement of the average predictive performance, which prevents a model that produces a less accurate prediction from heavily impacting the overall representative performance.

The relative scores between concepts are highly correlated across modeling methods. In other words, the concepts that had a high R^2 score for one model also had a high R^2 score for most of the other models. As shown in Figure 5, Concepts 4 and 5 have the highest R^2 value irrespective of the modeling method, and Concept 14 is on the lower end of R^2 values. This could be because of how well a gameplay feature predicts a concept is dependent on the type of concept. In other words, some concepts are harder to model irrespective of the modeling approach used for the model.

Interestingly, concepts that contained only a single question (i.e. 9, 11-12, 14) produced noticeably low R^2 values. These single-question concepts produced an average R^2 value of 0.046 across all the models. Because there was only a single question associated with the concept, each competency score was entirely dependent on students' single response to the question, which could result in a reliability issue in the competency scores due to students' behaviors related to guess and slip as well as a higher variance in the scores, together possibly attributing to these low R^2 scores.

A chart of the average student score for each concept based on their post-test performance is shown in Figure 6 below, distinguishing between single-question and multi-question concepts. The average student performance on multi-question concepts was markedly higher than for single-question concepts, with students achieving scores of 0.672 and 0.507, respectively. It was noted that the

average students' scores on the questions mapped to a single concept was remarkably low compared to an overall student score of 0.661 across all questions. This factor may also have impacted the predictive performance of the competency models compared to competency models that encounter fairly consistent or accurate student answers to post-test questions, as the questions corresponding to lower student scores introduce higher variance into the resulting competency scores used to train the models.

Finally, we investigate the impact that overlapping concepts may have on the performance of the classifiers. A concept is considered to be "overlapping" if it shares a correlated question with one or more different concepts. Out of the 16 concepts, 6 concepts were found to be "completely" overlapping; that is, every question associated with that concept was also associated with another concept. One concept was "partially" overlapping, indicating that only a portion of the associated questions were also mapped to another concept. The remaining concepts were the only ones that corresponded with their own associated question or group of questions. Student scores were significantly higher for overlapping concepts as opposed to non-overlapping questions, achieving average scores of 0.718 and 0.550, respectively. This trend is also present in our competency models, as the optimal models in our hybrid framework yield R^2 values of 0.339 (overlapping) and 0.157 (non-overlapping) on average. Surprisingly, the optimal models for the overlapping concepts were primarily single-task models, with the exception of one model. This indicates that multi-task modeling across all the concepts including both relevant and irrelevant concepts is actually detrimental in terms of achieving higher predictive performance. Thus, a promising future direction is to investigate multi-task learning performance by grouping relevant concepts and separately modeling related concepts only.

Figure 6. Student post-test performance on concepts associated with single and multiple questions.

In this particular application domain (genetics), concepts C1 and C2 are foundational to eight other concepts, as they describe a common pattern of gene variant behavior in inheritance of traits. Some concepts are related variously to other concepts, e.g., C5 requires deductive reasoning based on C1, C2, and C15, while it also serves as a prerequisite for C7, which allows determining gene variants for ambiguous traits. Alternatively, concepts C9-C12 focus primarily on molecular genetic inheritance and are not as tightly related to other concepts. This example of varying connections within genetics-related concepts illustrates the broader application of our hybrid model and why it demonstrates promise for other domains.

7. CONCLUSION

Stealth assessment holds considerable potential for game-based learning. Recent work exploring stealth assessment has typically

employed a single machine learning technique to devise competency and evidence models. This approach operates under the assumption that each student competency can be optimally modeled by the same learning algorithm that yields the highest predictive performance on average. However, this may not always be the case, as student competencies often have varying interleaving relationships with each other or even underlying complexities within itself.

In this work, we demonstrate the effectiveness of a hybrid stealth assessment framework consisting of a combination of single-task and multi-task models, using static and sequential features to represent student gameplay data. We evaluate our stealth assessment framework using a game-based learning environment and predict student competencies as measured by a post-test. Results indicate that a heterogeneous approach to stealth assessment modeling techniques induces higher results across all concepts when compared to the single-model baseline evaluations. Selecting a single competency model for all concepts based on its average performance across all the concepts is a common practice in stealth assessment frameworks. However, the proposed hybrid system using the optimal model for each individual concept returns a performance that is substantially higher than a homogeneous framework. In addition to static, single-task modeling, the sequential, multi-task modeling approach can adapt to multiple concepts by effectively capturing sequential context underlying individual students' gameplay behaviors, as well as simultaneously modeling various competencies that were manifested throughout the gameplay sessions. The use of all of the aforementioned modeling techniques provides a multi-dimensional approach that has been demonstrated to be a step forward in improving stealth assessment techniques.

There are a number of future directions that can be investigated to further improve the performance of the hybrid stealth assessment framework. Multi-task learning becomes increasingly difficult as the number of tasks increases and training deep sequential models for 16 tasks using only 316 data samples is likely a limiting factor in the multi-task models' performances. To gain further insight into the use of multi-task learning as a competency modeling technique, the hybrid stealth assessment framework presented in this work should be evaluated on comparatively larger datasets. This also enables the evaluation of the hybrid framework's ability to adequately translate to other student populations. Alternatively, different ways to reduce the number of tasks can be investigated. Due to the hierarchical, interweaving relationships within both individual concepts and between concepts and various questions, it will be worthwhile to investigate other sophisticated hierarchical modeling methods such as Bayesian hierarchical modeling or clustering methods, as well as refine the post-test questions and the mapping to the concepts to more reliably assess students' competency for each concept. Additionally, the feature engineering process performed for both static and sequential models can evolve significantly, possibly inducing higher performance from the competency models. Finally, it will be instructive to investigate the generalizability of this framework across different learning environments, contexts, and student populations.

ABSTRACT

Collaborative problem solving behaviors are difficult to identify and foster due to their amorphous and dynamic nature. In this paper, we investigate the value of considering early class period behaviors, based on small group development theory, for building predictive machine learning models of collaborative behaviors during problem solving. Over 12 weeks, 20 small groups of undergraduate students solved problems facilitated by a digital joint problem space tool on tablet computers, in the 50-minute discussion component of an engineering course. We annotated 16,270 video clips of groups for collaborative behaviors including task relatedness, talk content, peer interaction, teaching assistant interaction, and tablet usage. We engineered two subsets of features from tablet log file data: onset features (early collaborative problem solving behavior characteristics calculated from the first ten minutes of the class) and concurrent features (more general collaborative behaviors from the whole class period). We compared accuracy between the onset, concurrent, and onset + concurrent features in machine learning models. Results exhibited a U-shaped pattern of accuracy over class time, and showed that onset features alone could not be used to effectively model groups' collaborative behaviors over the entire class time. Furthermore, analysis did not show support for significant gain in accuracy when onset features were combined with concurrent features. Finally, we discuss implications for studying collaborative learning and development of software to facilitate collaboration.

1. INTRODUCTION

Collaborative problem solving consists of the communication and coordination of shared effort between team members toward a common desired goal [19, 23, 26]. Though it has been identified as a critical skill for students in the classroom [11, 34, 25], it is difficult to identify effective behaviors and nurture them, since the nature of collaboration and teams can be amorphous [48] and dynamic [43]. Education and learning sciences researchers have advocated for qualitative coding of video data as a means to understand the complexities of learning behaviors [24], and have applied these methods to study collaborative behaviors and the development of collaborative practices in courses [35]. Computers can further support collaborative learning research through collaborative learning software, collaborative games, and digital joint problem spaces—"a socially-negotiated set of knowledge elements, such as goals, problem state descriptions and problem solving actions" [44]—the resulting log data of which have been widely used with machine learning and data mining approaches to uncover hidden patterns of collaborative behaviors [31, 1, 37, 12]. Recent technological advances have also given way to multimodal approaches, using eye-gaze tracking, bodily motion, and physiological data to identify collaborative states [28, 40].

Despite such diverse approaches to detect and identify collaborative behaviors in learning contexts, the evolution of collaborative practices in student groups has not been closely investigated. Understanding the evolution of collaboration and its impact on methods for measuring collaboration is crucial, however. What constitutes collaborative behaviors may change throughout a learning session [10], and thus measurement may need to be adapted as well. In this paper we focus on the relationship between measurement and behavioral changes over time within classroom sessions. In particular, we leverage organizational theory about the sequential nature of small group development to inform research on how to measure and predict collaboration via machine learning in the presence of inevitable shifts in behaviors throughout collaboration stages.

The rest of the paper is organized as follows: we first discuss the small group development theories on structured, sequential group development which motivated our work, then relate

them to collaborative problem solving in the classroom to define our research questions and respective hypotheses. We then introduce the context of our study, including the collaboration tool, behavior coding, data processing, and model building. Next, we present our findings and close with an interpretation of our results and note limitations and future work.

1.1 Small Group Development

Research in organization and management fields on understanding how collaborative behaviors contribute to small group dynamics and development goes back several decades. Perhaps most notably, Tuckman's 1965 meta-analysis of therapy and human relations training groups presented the *forming-storming-norming-performing* (and later a fifth stage, *adjourning* [50]) model [49]. The model outlined the existence of a sequential, stage-based trajectory of small group collaboration, in which a group must fulfill one stage before advancing to the next. Tuckman's five model stages were described as (1) orientation to task (forming), (2) emotional response to task demands (storming), (3) open exchange of relevant interpretations (norming), (4) emergence of solutions (performing), and (5) separation (adjourning). This has led to decades of efforts to better understand the stages in various settings, including management [36], education [51], and medical training [47].

Tuckman's 5-stage structure of group development was further supported by Cassidy's 36-book meta-framework study, which aimed to clarify group development for practical use by examining group development in therapy, education, and management settings [17]. Though some scholars have presented theoretical models with more or fewer stages to group development [46, 21, 54], others have supported the five-stage model with differently termed, but analogous stages to Tuckman's model [16, 22, 8].

In nearly all proposed theoretical models of small group development, the first stage is defined as the task orientation stage [49, 16, 22]. During this stage, group members contextualize the task within the given parameters and communicate regarding the manner in which it will be accomplished [49]. While "ground rules" are set during this stage, communication about task orientation continues on some level throughout the collaboration process. Moreover, in problem solving, communication with references to others' ideas rather than independent solution paths has been identified as an important marker of shared task alignment, or "establishment of a collaborative orientation toward problem solving" [4]. In this study, we briefly analyze transitions across the stages of small group development during problem solving in classrooms. However, we focus much more closely on the first stage, orientation to task, since it has been shown to have a significant positive effect on achievement [45]. The first stage characterizes cooperative orientation and the motivation to collaborate, which has a strong relation to the quality of collaboration [13].

1.2 Contributions and Novelty

This paper considers the role of early group behaviors in collaborative problem solving. We investigated whether explicitly incorporating early group behaviors as features improves machine learning predictions of collaboration and

analyze how model accuracy evolves across time and stages of collaboration.

We used qualitative coding of collaborative behaviors on video data to measure collaboration. We then predicted those behaviors from features extracted from the action log files of a digital collaboration tool (run on tablet computers) used by undergraduate students in an introductory mechanical engineering course at a large Midwestern U.S. research university. We created various feature subsets and built corresponding machine learning models to evaluate the predictive accuracy of early group behaviors versus behaviors from later on in class periods. Assuming the presence of sequential, evolving collaborative behaviors in small groups, and the importance of early collaborative behaviors, machine learning models created from considering class behaviors as a whole may potentially be improved by accounting for early behaviors. For example, a group of students who fail to form a successful collaborative dynamic early on may struggle throughout class, whereas a group of students who exhibit high collaboration early on may be more effective in later stages. Consequently, we analyze whether a model built on features from class behaviors as a whole would have variable performance for collaborative behaviors predictions over the different segments of the class period, which align with the different stages of group development.

We aim to understand how effective collaborative behaviors, relating to orientation to task, during earlier stages may influence a group's collaborative behaviors in the future. As such, we also compare the performance a model solely built from such earlier features with one built from features of behaviors from all current and past in-class behaviors, not just early-stage behaviors.

We approach the aim of this paper by formulating and addressing several research questions:

RQ1 How does the predictive accuracy of collaborative behaviors vary across different periods of a 50-minute class?

Hypothesis: We expect stages of collaboration that are dominated by tablet computer interaction behaviors (e.g., reading, drawing) will be more successfully predicted than those dominated by discussion, and that the changing base rates of collaborative behaviors over time will influence classification accuracy [29].

RQ2 Can early class collaborative behaviors alone be used to effectively model and predict collaborative behaviors of the entire class period?

Hypothesis: We expect early class behaviors to predict the quality of collaboration later in class if and only if groups' collaboration quality remains static or consistently mirrors early collaboration.

RQ3 Are collaborative behavior prediction models improved through emphasizing early class collaborative behavior features?

Hypothesis: We expect prediction models will be more accurate later in class periods if early class behaviors capture

groups that are consistently collaborative or consistently not collaborative.

2. RELATED WORK

In this study, we utilized video coding methods along with machine learning approaches for analyzing action log data to study temporality. Work in computer-supported collaborative learning (CSCL) has highlighted the importance of considering temporality in collaboration, and Reimann has argued that “the main object of analysis in CSCL is a process—something that unfolds over time” [42]. For example, Mercier et al. examined through video coding and counting how the development of collaborative practices in engineering courses evolve over four weeks, and saw that patterns of interactions, such as conversation and workflow, change over time [35]. Others highlighted the value of utilizing more complex quantitative methods over video coding methods to consider temporality in analyzing problem-solving processes in computer-supported collaboration settings, as it can reveal aspects of group interactions that coding methods cannot reveal [32].

Collaborative learning may also be effectively analyzed via the action logs, discourse data, and gameplay data of digital tools and serious games, which are able to provide fine-grain recollections of the learner’s interactions with the respective software. Educational data mining researchers have applied supervised [41] and unsupervised [14, 31] machine learning techniques to better understand collaboration and to inform the design of interventions to support collaborative learning through such means as software prompts [31] and content creation suggestions [52]. Additionally, Paquette et al. have highlighted the need to support students during collaborative learning by considering the role of the instructor in facilitating student collaboration [38]. As such, instructor dashboards have been explored as ways for instructors to more easily gauge and analyze student collaboration across multiple groups [3, 33]. A central aim of our study has been to inform better instructor interventions for facilitating collaboration through insights gained from analysis of action log data.

3. METHODS

This study utilizes data collected from a design-based implementation research project which aims to better facilitate collaboration in engineering problem solving through the analysis of video and interactions from engineering classes. The project team has developed a student-facing tool that facilitates student group collaboration through a synchronized-per-group shared digital environment (Figure 1) on tablet computers, which group members can use to create and display their work. During use, we collected two types of data: student interactions on the tool stored in log files—detailing actions taken by individual students such as writing, drawing, or editing—and video data from cameras set up around the classroom. One of the key goals of the tool is to scale to large classrooms where cameras are unlikely to be consistently available; thus, we utilize video data to collect ground truth labels, but rely only on logged tablet actions for collaboration prediction.

Data in this study came from the use of the tool in Fall 2017 during the discussion component of an undergraduate intro-

Figure 1: One example of the result of collaborative problem solving through the tool’s shared digital environment. The interface allows students choices of different colors and tools to write, draw, and create figures.

ductory mechanical engineering course at a large Midwestern U.S. research university. The research team worked closely with faculty and teaching assistants (TAs) to design tasks suitable for collaboration and in line with the intended learning outcomes from the class. The tasks were independent from week-to-week and did not build on one another, and the students were not graded on completion by the end of each class period. The tasks were represented in the tablet tool as worksheets with variable number of pages, which included problem descriptions and space to work out solutions. Data were collected across 12 weeks of class from 20 groups of approximately 4 students (group sizes varied from week to week based on attendance).

While students interacted on tablets using the interface shown in Figure 1, TAs present in the classroom viewed student progress on their own tablets (Figure 2). The TA tablets showed students’ editing positions in the worksheets, and allowed TAs to join any group as a non-interactive participant to see students’ work in detail. Our current work seeks to augment the TA-facing tool via predictions of various markers of collaboration quality made by machine learning models. This feature enables TAs, who may lack extensive training in assessing and promoting collaboration, to identify groups that are not collaborating well and intervene to encourage collaboration.

3.1 Behavior Coding Process

Videos of each group’s interactions (Figure 3) were captured by high-angled cameras and synchronized with audio data captured by microphones positioned near each group; additionally, an overhead fisheye lens camera captured the entire class, including events such as the TAs’ interactions with groups. The collected video data were annotated (coded) at the group level by two trained annotators with an annotation scheme adapted from previous work on collaborative behavior annotation [38] to define group activity in terms of task relatedness, peer verbal interaction, TA interaction, talk content, and tablet usage.

Previous research on predicting collaboration from interactions with software has involved annotating similar content

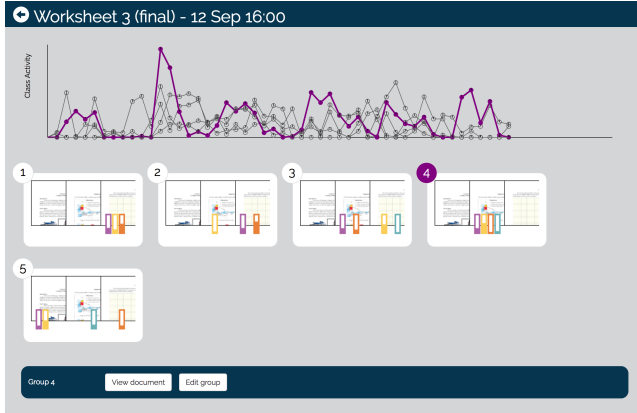

Figure 2: Example screenshot of a teaching assistant’s view of a classroom with five groups of students. The top graph indicates activity over time for each group, with the selected group (#4) highlighted in purple. Bars on each worksheet thumbnail show the page each student is viewing and their individual levels of activity.

Figure 3: An example of a group working collaboratively on a problem through the tool on tablet computers. Videos of such groups were recorded and qualitatively coded through a coding scheme adapted from Paquette et al.’s work [38].

in video clips at 60-second intervals [38]. In this study, the presence of collaborative behaviors (expanded below) were annotated at 20-second video clips, after trials of the annotation process at different clip duration of 10, 20, 30, 40, and 60 seconds. Annotators determined 20 seconds to be a reasonable balance—10 seconds was too brief to confidently observe the presence of collaborative behaviors, while 30 seconds was too long and often led to the observance of multiple collaborative behaviors within the same video clip. Furthermore, through our trials at varied clip lengths, additional identifiable behaviors emerged that were better identified at the current 20-second coding clip length rather than the longer 60-second clips annotated in previous work. A total of 16,270 clips were annotated for the presence (annotated as 1), or absence (0) of the following set of collaborative behaviors:

- *Task relatedness*: At least one of the group members appears to be on task (e.g. two students solving problems on the tablet).
- *Peer verbal interaction*: Verbal interaction is present between group members.
- *TA class interaction*: TA is talking to the whole class (e.g., class-related announcement, addressing a frequently asked question).
- *TA group interaction*: TA is verbally interacting with at least one of the group members.
- *Task talk*: Audible talk content in the group is related to solving the task.
- *Other talk*: Audible talk content in the group is not related to solving the task.
- *Tablet movement*: At least one of the group members is moving the tablet to initiate (and to end) sharing of the screen content with others.

We measured inter-rater reliability via Cohen’s kappa [18] and percent agreement on a subset of 2,125 video clips. Table 1 shows these reliabilities. All labels except *Other talk* (kappa = .651) achieved kappa = .8 or higher, indicating substantial agreement [18]. Given this agreement, the two annotators divided the remaining 14,145 clips and annotated them individually.

Table 1: Inter-rater reliability for a sample of 2,125 video clips in this study.

Behavior	Base rate	Agreement	Kappa
<i>Task relatedness</i>	.954	98.6%	.840
<i>Peer verbal interaction</i>	.501	91.7%	.833
<i>TA class interaction</i>	.024	99.5%	.898
<i>TA group interaction</i>	.150	98.3%	.932
<i>Task talk</i>	.608	91.2%	.816
<i>Other talk</i>	.072	95.3%	.651
<i>Tablet movement</i>	.019	99.2%	.801

Of the qualitatively coded behaviors, we considered six specific behaviors for this study: ON-TASK (derived directly from *Task relatedness*), ON-TASK-NO-INTERACTION (from a combination of *Task relatedness* and *Peer verbal interaction*), PEER-INTERACTION (from *Peer verbal interaction*), SILENT (from *Task talk* and *Other talk*), TASK-TALK (from *Task talk*), and TA-CLASS (from *TA class interaction*). These six behaviors were those which we believed would be best suited for investigating the evolution of collaboration with consideration of the actions of both the TA and students during a typical class period for the course. We did not include tablet movement due to the low base rate during annotation and questionable value for characterizing collaboration. We deemed ON-TASK-NO-INTERACTION important for distinguishing collaboration from individual work, and while it was not explicitly annotated, it was calculated from a combination of two different behavior labels (*Task relatedness* and *Peer verbal interaction*).

3.2 Data Processing

The tablet tool collected student action log files, one per group, during each class session. Relevant behavior data were cleaned and stored based on expected suitability for predicting collaborative behaviors on the tool. These types of data included event types, such as scrolling, drawing, object creation (inserting one of a few built-in graphics), modifying drawings or objects (removing or undoing), as well as the size and position of edits made, object geometry changes (e.g., moving, resizing), page number, scroll bar position, and changes to drawing color.

3.3 Machine Learning Models from Feature Subsets

We aligned annotated behaviors with the student action log files to allow synchronized analysis between the two data sources. We created three features sets: (1) *onset* features, which characterized collaborative behaviors found in and calculated within the first ten minutes, (2) *concurrent* features, which captured collaborative behaviors based on the most recent 60 seconds as well as all cumulative data, and (3) *combined* features, which combines both subsets. Student behaviors were recorded individually within each group's log file. However, we primarily extracted features intended to characterize whole-group behaviors, in line with the group-level video annotation scheme and the overall project goal of improving collaboration rather than individual learning behaviors.

3.3.1 Feature Engineering

Designing features to extract took place over the course of several sessions involving the video annotators and researchers, who discussed behaviors observed in the classroom and how they might be reflected in tablet-based behaviors.

We extracted 89 features from the action logs using the full 50-minutes of the class duration, which we refer to as concurrent features. For these features, we used a combination of the behaviors that annotators had observed to be related to collaboration, as well as those characteristics we hypothesized to be more broadly associated with effective collaboration. For example, we created features such as: the mean distance between consecutive edits of the same students (since it may

distinguish working in one area vs. jumping around rapidly), total number of unique document pages viewed (a higher number may symbolize more exploration of the task), and maximum distance between concurrent edits of the same page but made by different students (may symbolize task division).

Similarly, we extracted 21 features from the action logs calculated from the first ten minutes of class, which we refer to as onset features. Assuming the five stages of small group development apply in this context, we approximately split each 50-minute class period into stages by dividing into fifths. We expected each class period to somewhat reset the collaboration process, since there was a new task each week—meaning a new corresponding task identification stage (storming), as well as some variation in the group, in number and person, due to fluctuating attendance. We specifically kept in mind the characteristics of the task identification stage, such as verbal and written communication for contextualizing the problem and setting “ground rules”, as well as behaviors such as reading or using visual figures to understand (but not necessarily solve) the exercises. To that end, we created features such as: the proportion of the first ten tool objects created by the group being the pre-made available diagrams (a higher proportion may mean more complete solutions early in class), the longest time between object additions and edits (longer pauses between actions may characterize more verbal communication), and the cumulative number of page switches (switching back and forth between pages may signal wanting to fully understand the task at hand by referencing material on other pages).

3.3.2 Machine Learning and Cross-Validation

We used the random forest classifier in the scikit-learn Python library to build models from each respective feature subset [39]. We selected random forest due to its effectiveness in dealing with high dimensional feature spaces, and reducing overfitting [27, 9]. It is also able to deal with highly correlated features, and provides feature importance measurements which we analyzed to find the features that were most predictive of collaboration. We cross-validated models via leave-one-group-out (each of the 20 groups used as the testing set once), and tuned hyperparameters using nested cross-validation and grid search within training data only. Hyperparameters consisted of the proportion of features to consider for each tree branch (0.25, 0.5, 0.75, or 1.0) and the minimum number of instances required in a tree node to create new branches (2, 4, 8, or 16).

Table 4 presents the values of r_{pb} , kappa, and area under the receiver operating characteristic curve (AUC) of the models, cross-validated over all data ignoring the five collaboration phases. We decided to use the point biserial correlation coefficient, r_{pb} , of the true and predicted values as the primary accuracy metric, since the extreme base rates of ON-TASK and TA-CLASS behaviors (and the changing base rates of other behaviors over collaboration phases) led to unwanted sensitivity to the threshold for kappa calculation. Kappa scores (without threshold tuning) were not necessarily representative of accuracy changes as much as poorly-chosen decision thresholds. Table 4 shows that the pattern of AUC values across behavior labels was similar to r_{pb} ; however, r_{pb} allows straightforward computation of confidence intervals, enabling

Table 2: Top ten most important features for each of the six considered collaborative behaviors from the combined features (onset + concurrent) random forest model. Common features in all six behaviors are in bold.

ON-TASK	ON-TASK-NO-INTERACTION	PEER INTERACTION
1. maximum seconds of no actions	1. number of actions	1. cumul. number of page changes

10. cumul. number of scroll position changes	10. cumul. ratio of 2nd most to most active	10. cumul. number of selection changes

the statistical comparisons of models that we include in this paper. We thus proceeded with r_{pb} as the primary accuracy metric.

4. RESULTS

Within a 50-minute class period, we surmised that the five stages of a collaborative problem-solving team could be approximated through five equal 10-minute segments. However, if base rates of each behavior vary over time, model accuracy could as well [29]. Thus, before answering our research questions, we visualized the base rates of each behavior to help inform the results.

4.1 Base Rates Over Time

The trajectories of average base rates of the collaborative learning behaviors across these five segments of class are shown in Figure 4. Across behaviors, we observed a common pattern: the largest changes in base rates were from the first 10-minute segment to the second. The magnitude and direction of the changes in base rates during this transition were variable between the different behaviors, though some patterns can be assumed to be closely correlated. For example, the behaviors TA-CLASS and SILENT followed a similar negative trend in magnitude, since students across groups are more likely to be silent when the TA is addressing the entire class at the start of the class period, when task objectives or announcements are likely to be made. Similarly, ON-TASK, PEER-INTERACTION, and TASK-TALK tended to increase during class periods, since ON-TASK behavior is likely to involve more instances of PEER-INTERACTION and TASK-TALK behavior. ON-TASK-NO-INTERACTION showed a comparatively consistent base rate throughout the class period, perhaps being influenced by other behaviors in both directions with similar magnitude.

As base rates become more imbalanced (closer to 0 or 1),

Figure 4: Average base rates of annotated behaviors across segments of each class period (averaged across class periods).

classification problems tend to become more difficult because fewer data points are available from one category of the data, and because accuracy metrics tend to become less effective [29]. Hence, the patterns in Figure 4 are important to consider when interpreting the results of the research questions.

4.2 RQ1: How does the accuracy of predicting collaborative behaviors vary across periods of a class?

To address this research question, we focused on the accuracy of the concurrent features model. This model has similar accuracy to the combined features model (see RQ3), and is more parsimonious since it has 89 features, compared to 110 features from the combined model. Thus, it will likely be the model of choice to drive predictions in future versions of the TA-facing tablet tool, and we focus RQ1 on this model.

Figure 5: Concurrent features model accuracy shown over time throughout five segments of classes. Accuracy in this case consists of point-biserial correlation coefficients with 95% confidence intervals indicated by shading or by error bars for labels where base rates were too imbalanced (0% or 100%) to allow prediction in every class segment.

From the overview of the model performance in Figure 5, a general U-shape pattern can be observed across the class period, where the second peak in accuracy toward the end of class never quite reached the initial accuracy from the first ten-minute segment. This trend differed for ON-TASK-NO-INTERACTION, which showed a rapid drop after the first 10-minute segment, from 0.351 to 0.062, and did not later increase. Predictions for ON-TASK-NO-INTERACTION and SILENT also briefly dropped below chance level during the second half of the class period.

4.3 RQ2: Can early class collaborative behaviors alone be used to effectively model and predict collaborative behaviors of the entire class period?

As shown in Figure 6, the onset features model had overall lower accuracy across the class periods compared to the concurrent features model (Figure 5). The absence of the U-shaped pattern from the concurrent features model (Figure 5) suggests that the first 10 minutes of collaborative behaviors may have been sufficiently similar to be captured by a model with features created from behaviors from the entire class duration, but that those behaviors were not the same as the last 10 minutes. With the exception of SILENT, predicted behaviors showed a trend toward the lowest accuracy at the end of class. However, PEER-INT remained significantly above chance for the first 30 minutes of class, indicating that groups’ verbal interactions were—to a certain extent—characterized throughout most of the class period by their first 10 minutes of logged behaviors. When compared to the accuracy pattern for the concurrent model, (Figure 5), accuracy dropped below chance level more often, with ON-TASK-NO-INTERACTION, TASK-TALK, and SILENT behaviors predicted at below chance level for the latter half of the class period.

Figure 6: Point-biserial correlation coefficients with 95% confidence intervals by class segment for the onset features model.

4.4 RQ3: Are collaborative behavior prediction models improved through the addition of early class collaborative behavior features, leading to a greater emphasis on the early class period?

The lower and upper 95% confidence interval bounds of the point-biserial correlation values of the models are presented in Table 3. Among the confidence intervals there was overlap for concurrent vs. combined models, but not for onset vs. concurrent and onset vs. combined (with the exception of TA-CLASS for onset vs. concurrent, not drastically so), highlighting that there was no clear significant difference in the models from the addition of onset features to the concurrent features model. This is further supported in Figure 7, which shows that the trajectory of the combined model accuracy closely resembles the concurrent features model (Figure 5). Table 4 also shows that in most cases the combined feature set was not notably better than concurrent features alone when considering overall accuracy across class time segments, in terms of $r_p b$, kappa, or AUC. Feature importance were analyzed and are presented in Table 2. Three common features were found in all six behaviors: *cumulative number of set page*, *cumulative number of scroll position changes*, and *cumulative number of rows*.

5. DISCUSSION

We analyzed automatic detection of collaborative problem solving in classrooms through a lens informed by small group

Table 3: Comparison of the 95% confidence intervals of the models’ point-biserial correlation coefficients, r_{pb}

	Onset	Concurrent	Combined

development theory. Based on the five stages of small group development and the importance of the early periods of collaboration, we were curious if explicitly considering early class behaviors was beneficial for predicting a team’s collaborative behaviors over a class period. We annotated collaborative behaviors from 16,270 video clips of an undergraduate engineering course as ground truth for behaviors, and compared the accuracy of a machine learning model built from onset features (early collaborative behaviors calculated from the first ten minutes of class) to a model from concurrent features (general collaborative behaviors over the whole class period). In this section, we discuss the implications of our findings.

5.1 Collaboration Across Class Periods

We investigated whether evidence of the five stages of group development could be seen in the concurrent model accuracy when examined in 10-minute periods of a 50-minute class. Our experimental results showed a U-shaped accuracy curve for a majority of the considered collaborative behaviors, with lowest accuracy in the middle 30 minutes of class. The base rate trends (Figure 4) may be one explanation for the observed pattern, because a majority of the behaviors also had U-shaped or inverse U-shaped base rate patterns, which is indicative of unbalanced classes. An exception to the U-shape for accuracy and base rates was ON-TASK-NO-INTERACTION, which had the highest accuracy at the beginning of class and lowest by the end. One possible explanation for this may be that the students in the first 10 minutes of the class were reading or individually thinking about the task, and transitioning to become more verbal and interactive as the class goes on—which can be approximately observed in the overall base rate pattern.

In terms of the small group development theories, the U-shape may be interpreted as evidence for the existence of three, as opposed to five, distinct stages: a beginning, a longer middle, and an end. Three stages is in line with Spitz and Sadock’s three-stage model from observing the training of nursing students [47]. According to the model, stage one is characterized by anxiety-related emotions, such as curiosity and confusion, stage two is a period of trust and cohesiveness, and stage three is disengagement and anxiety about the group conclusion.

It is difficult to determine whether these stages were captured in our analysis, however, since there were some notable dif-

Table 4: Accuracy comparison of the onset features, concurrent features, and combined features (onset + concurrent) models.

Behavior	Model	r_{pb}	Kappa	AUC
ON-TASK	Onset	.470	.469	.737
	Concurrent	.532	.529	.746
	Combined	.547	.545	.754

	Concurrent	.445	.424	.699
	Combined	.422	.407	.692
TA-CLASS	Onset	.011	.008	.503
	Concurrent	.064	.024	.507
	Combined	.095	.036	.510

ferences in context and aim between our study and Spitz and Sadock’s research. In our study, we did not set out to capture or identify emotions during collaboration, since the focus in data collection was on annotating collaborative behaviors and capturing action data, such as tool use, scrolling, and editing. Furthermore, while previous work has developed approaches for detecting student affect through applying computer vision techniques to detect facial expressions and bodily movements on video [15, 53, 6, 7], our study used video data as means to obtain ground truth data for collaboration rather than emotion. A central goal of our research is to enable analysis for real-time collaboration intervention in the classroom, and thus we analyzed ways to detect collaboration using solely action log data, which can be applied in large and varied classroom environments even when sensors are not available. Current methods for accurately capturing emotion during learning largely rely on video or multimodal methods [5, 20], and it is difficult to envision classrooms with access to multimodal instruments and camera systems designed for analyzing emotion and collaboration.

5.2 Role of Early Collaborative Behaviors

Our hypothesis that early class behaviors could effectively predict the quality of collaboration later in class was not supported by our findings. While we created onset features with characteristics of task identification of problem solving, such as verbal communication, deliberation, and reading, through features such as handwriting on the tablet, pauses between edits, high number of object removals, frequent page switches, and problem diagramming, the accuracy of the onset features model was lower than the concurrent model as a whole. Moreover, the U-shaped pattern from concurrent

features model was not observed. Despite the accuracy of the onset model showing a similarly steep decrease after the first ten minutes, it did not increase at the end of the class for any of the considered collaborative behaviors, as had the concurrent model. Taken together, the U-shape of concurrent model accuracy and the steep decline in accuracy of the onset model suggest that the first ten and last ten minutes of class are similar, but there are differences which make it difficult to effectively characterize based on features calculated from the first ten minutes of class. The similarities of the first and last ten minutes are also supported from the trends in the base rates (Figure 4). TA-CLASS behaviors—when the instructor addresses the entire class—only tend to occur at the beginning and end of class, but the content of the announcements at the beginning of the class are different and likely influence student behavior differently. For example, students may be more likely to listen and be silent in response to the announcements made at the beginning of the class since it is immediately pertinent to the class ahead, but students may be less silent when announcements are made at the class end.

Our analysis also did not support the idea that the addition of the onset features (21 features) to the concurrent features (89 features) model might improve predictive accuracy. While the resulting combined model was created using the largest number (110) of features with an emphasis on the earlier parts of class, the accuracy did not differ significantly from the concurrent features model. Comparing the confidence intervals of the model’s overall point-biserial correlation coefficient (Table 3) showed that while the accuracy of onset and concurrent features models are significantly different for a majority of the behaviors except TA-CLASS (which has especially imbalanced base rates), there is overlap between concurrent and combined models for all behaviors. This indicates that the models may not be statistically different, and are not meaningfully different. Moreover, of the 110 features in the combined (onset + concurrent) model, none of the 21 onset features were found in the top ten important features in any of the six behaviors (Table 2). Three common features were found in the top ten important features for all six behaviors: *cumulative number of set page*, *cumulative number of scroll position changes*, and *cumulative number of rows*. When interpreted together, these three features may be related to the overall activity level of the groups, which may intuitively relate to changes in collaborative behavior.

6. CONCLUSION

In this paper, we were motivated by theories in small group development to analyze how explicitly accounting for early class behaviors and collaboration evolution might help improve collaboration prediction from tool action log data. We investigated collaborative problem solving in an introductory engineering course over 12 weeks. We found that collaboration prediction in a 50-minute class period did not appear to follow a straightforward interpretation of the five-stage structure, but rather a potential three-stage structure. We found that while the first ten minutes of class are distinct from the middle and ending periods of class, onset features calculated from the first ten minutes of the class could not be used to effectively predict collaboration in the later parts of class. Concurrent features (calculated from the whole 50-minute period) performed better as a whole, and the combination

of onset and concurrent features did not necessarily lead to a better predicting model. Thus, groups’ collaborative behaviors later in class were not notably related to their initial collaborative behaviors.

Our study was limited in several ways. Using solely tablet action log data to examine small group development restricted us from being able to account for changes in emotion, a common aspect of small group development theory. We utilized data from action logs since we wanted our analysis to be scalable and make progress toward real-time student interventions for collaboration in the classroom via prompts delivered to TAs (Figure 2). However, to promote better understanding collaborative learning theory in general, additional approaches are needed. To this end, future work examining small group development in collaborative problem solving may benefit from incorporating work on sensor-free affect detection for student engagement [2, 30], which may help identify emotions associated with various stages of small group development such as confusion or anxiety [47]. Additionally, audio of group conversations could be recorded from their tablets and aligned with action log data to understand conversations in the context of the small group development at hand. Our study was also limited by the variability of student groups in size and membership. Some groups had as few as two students in some weeks of class, and the same groups may have had four members in other weeks. This likely influenced the amount of activity captured, in addition to inevitable changes in the communication dynamic.

Insights into the influence of early collaborative behaviors for improving collaboration prediction may help design better interventions for helping TAs facilitate collaboration, and design software tool features to promote effective student collaboration. Deeper insights into understanding small group evolution may offer ways for future work to more accurately identify a group’s current collaborative stage solely from a group’s behaviors, without considering content of interactions between members. Based on the assumed stage, instructors or tools could possibly allow for personalized per-team interventions to better facilitate collaborative problem solving.

ABSTRACT

Data mining of course enrollment and course description records has soared as institutions of higher education begin tapping into the value of these data for academic and internal research purposes. This has led to a more than doubling of papers on course prediction tasks every year. The papers often center around a single prediction task and introduce a single novel modeling approach utilizing one or two data sources. In this paper, we provide the most comprehensive evaluation to date of data sources, models, and their performance on downstream prediction tasks. We separately incorporate syllabus, catalog description, and enrollment history data to represent courses using graph embedding, course2vec (i.e., skip-gram), and classic bag-of-words models. We evaluate these representations on the tasks of predicting course prerequisites, credit equivalencies, student next semester enrollments, and student course grades. Most notably, our results show that syllabi bag-of-words representations performed better than course descriptions in predicting prerequisite relationships, though enrollment-based graph embeddings performed substantially better still. Course descriptions provided the highest single representation accuracy in predicting course similarity, with descriptions, syllabi, and course2vec combined representations providing the highest ensembled accuracy on this task.

Keywords

Higher education, course recommendation, course2vec, prerequisites, enrollment histories, syllabus, network embedding, grade prediction, institutional analytics.

1. INTRODUCTION

Data from institutions of higher education are quickly coming into focus for educational data mining and learning analytics communities as the utility of these data start to become clear and attention begins to shift from the informal learning context of free online courses to the higher stakes context of degree granting institutions and their students.

WeiJie Jiang and Zach Pardos "Evaluating sources of course information and models of representation on a variety of institutional prediction tasks" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 115 - 125

Educational Data Mining (EDM) plays an important role in the developing stages of methodological adaptation to a domain by evaluating new sources of data for their utility in existing models and tasks and updating the utility of existing data as models and tasks evolve. Recently, EDM has seen a more than doubling year-to-year in papers focused on prediction with large institutional enrollment sets from the formal higher education context, with a single paper on the topic in 2017 [38], two in 2018 [12, 6], and five in 2019 [29, 36, 19, 37, 16], though early pioneering work on predicting academic outcomes date back to the first EDM conference [39, 2].

In this paper, we summarize and evaluate this quickly developing domain across three dimensions: sources of institutional data, models for representing students and courses, and the performance of the former two categories on institutionally relevant prediction tasks. As academic researchers and practitioners know, not all sources of data are always available and different costs are associated with obtaining a new source. Similarly, when it comes to modeling, different personnel and computational costs are associated with applying models depending on their complexity and recency of introduction. We provide the most comprehensive evaluation to date of the performance of different combinations of data and models on common institutional tasks emerging in the literature so that the costs and benefits of each, in our setting, can be quickly appraised. In addition to evaluating previously introduced approaches and data, we introduce large scale syllabus data as a novel source of information about courses and a novel application of a nascent graph-embedding approach for representing courses.

2. RELATED WORK

Contemporary approaches to data mining institutional datasets in higher education have distinguished themselves from earlier drop-out detection work [18] in the use enrollment data and adoption of representational methods that factorize, embed, or otherwise vectorize courses into a space. This began with [10] that used matrix factorization applied to student enrollments and observed that the factorization grouped courses and students in semantically meaningful ways. Subsequent research also employed matrix factorization for grade prediction tasks [38, 37]. Neural embedding models followed, with the skip-gram neural network model applied to sequences of course enrollments, an approach coined "Course2vec" [32]. The course embeddings extracted from this model were found to be predictive of on-

Table 1: Related work on institutional prediction tasks (columns) and sources of data used in the task (rows)

	Grade prediction	Enrollment prediction	Prerequisite prediction	Course similarity
Course grades	[10, 15, 21, 38, 37, 16]	[10, 3, 32, 36]	[22, 11, 21, 16]	[17, 25, 12, 29]
Enrollment histories	[10, 15, 21, 38, 37, 16]	[10, 3, 32, 36, 1]	[22, 11, 21, 16]	[17, 25, 31, 33, 29]

Catalog descriptions		[32]		[26, 31, 33, 12, 29]

time graduation [25], course similarity within [33] and across institutions [31], and of latent topics of courses [8]. Student course selections have also been posed as a graph, treating courses as nodes and student course selections as strengthening the edges between courses the more frequently they share students in common [15, 16, 1]. The aforementioned approaches all use student course selections, a collaborative signal, to represent a course. Other approaches utilize content data of a course (e.g., catalog description) for representation and for downstream tasks such as course similarity analysis [26, 31, 33, 12, 29] and enrollment prediction [32]. Several papers have collected course ratings for modeling and recommendation [13, 12].

The majority of models in related works have been framed as potentially contributing to a course recommendation system, or already integrated into one. They commonly focused on grade prediction [10, 15, 21, 38, 37, 16] as a necessary first-step towards a preparation, or goal-based [21] recommendation system that could aid students in preparing for difficult courses. In a similar vein, prerequisite course inference has been framed [22, 11, 21, 16] also as a potential means to help guide students towards course taking paths expected to be more successful than others [11, 30]. Table 1 summarizes this body of work in terms of the most common data sources used (i.e., course grades, enrollment histories, major declarations, and catalog descriptions) and most common evaluation tasks (i.e., grade prediction, enrollment prediction, prerequisite prediction, and course similarity) focused on in this paper.

3. DATA SOURCES

In this section, we will describe the three primary sources of data utilized in this paper. First, we will describe the source generally, followed by a paragraph detailing the particulars of the dataset used in our offline evaluation experiments.

3.1 Enrollment histories and grades

A student’s transcript is classically a report containing the student’s histories of courses taken and the grade achieved in each. Enterprise database systems often store raw forms of these data. It has become more common for institutions to not only store these data in relational form but for their internal offices of institutional analytics to have ready access to them. As the fields of EDM and learning analytics have grown, these data have become more available to faculty to aid scholarly research. We used an anonymised enrollments and grades dataset containing student enrollment histories at a large public university, UC Berkeley, collected from Fall 2008 through Fall 2017. The dataset consists of per-semester (i.e., Fall, Spring, and Summer) class enrollments for 164,196 students (both undergraduates and graduates) with a total of 4.8 million class enrollments. A class enrollment record in the data indicates that the student was still enrolled in the class at the end of the semester. The action of drop-

ping a class is not contained in these data. The median number of classes enrolled by a student in a semester was four. There were 9,478 unique lecture courses from 214 departments hosted in 17 different Divisions of 6 different Colleges. Course meta-information was also included in these data and contained course number, department name, class instructor(s), and room max capacity. In this paper, we only consider lecture courses with at least 20 enrollments total over the 9-year period, resulting in 7,487 courses. Although courses can be categorized as undergraduate courses and graduate courses, undergraduates are allowed to enroll in many of the graduate courses. Enrollment data were sourced from the campus’ enterprise data warehouse.

3.2 Course catalog descriptions

A paper catalog use to be the primary way in which students could browse all the course offerings at an institution. Fortunately, this has been superseded by online catalogs, most of which are searchable. The catalog contains course numbers, their hosting department, and typically a paragraph or type description of the course. Our dataset contains the most recent catalog description of every course in our enrollment histories. The average catalog description length was 325 words with 489 courses having exceptionally short descriptions of 10 words or fewer. We sourced these descriptions from the campus Office of the Registrar official API for Course information. These descriptions were pre-processed by (1) removing generic, often-seen sentences across descriptions (2) removing stop words (3) removing punctuation, and (4) word lemmatization and stemming.

3.3 Course syllabi from the Learning Management System

A course syllabus is a detailed, chronological list of subjects and assignments that a course will cover, often with other logistical information about course meeting place and time and grading policies. While the syllabus is perhaps an ideal source of information to utilize for content-based representation of a course, it has been an elusive source to conduct research on. This is because few institutions mandate that instructors make their syllabi public and therefore it is uncommon to have syllabi centrally stored by the institution to subsequently make available to researchers. An additional barrier to research availability is that many institutions view a syllabus as an instructor’s intellectual property (IP), and therefore not sharable in original form without permission. Our study introduces syllabus data into contemporary predictive models and tasks, but with a caveat that maintains instructor control over the original intellectual property.

The university from which our syllabus data come from considers syllabi to be instructor IP and does not collect them centrally. However, a common place in which instructors often place their syllabi is the “Syllabus” page of the cam-

pus Learning Management System (LMS). We worked with the campus technology services organization in charge of the LMS to extract all text from the Syllabus pages of all courses. Sometimes this page would contain only a link to the pdf of a syllabus, in which case that link was downloaded and parsed to text. To abide by the IP restrictions around course syllabi and respect instructor ownership of them, a workaround was arranged. Only the technology services would have access to the cleanly parsed data from the LMS. They would then pre-process the syllabus themselves, similar to how we pre-processed catalog descriptions, parsing out html, converting it into bag-of-words (BOW) form. This form would thereby make the syllabus unusable as an instructional object but potentially usable by an algorithm attempting to extract information for institutional prediction tasks. It was also agreed that the BOW we received would not be made public and these data could be revoked at any time. There were 3,645 unique courses that contained HTML on the LMS Syllabus page, not including a link to a file. There were 2,712 courses that contained a link to a file, with some courses having both. The total number of courses with some amount of syllabus data was 4,017 with a combined vocabulary of 17,194 unique words.

4. REPRESENTATION MODELS

We choose four approaches of increasing complexity for representing courses. These four reflect the most common paradigms of modeling found in our literature review. The simplest is a content-based bag-of-words representation of the course. The BOW approach could be applied to the catalog description or syllabus of a course, where available. Next is the use of a recently published variant on Course2vec called multifactor Course2vec, which applies a skip-gram to sequences of course enrollments. In addition to embedding courses, multifactor Course2vec also embeds the instructor of the course and the course's department, both presented to the model in the form of a one-hot encoding. Multifactor Course2vec has been shown to perform better on course similarity tasks than the original Course2vec [33], in theory because it separates out factors, such as instructor and department, allowing the course embedding to more purely represent the content. Long Short-Term Memory models are the third model used to embed courses, followed by a recently introduced network embedding technique.

A summary of the approaches used is visually illustrated in Figure 2. The various types of information these methods leveraged are summarized in Table 2.

Table 2: Summary of representative learning methods for courses

	catalog descriptions	course syllabus	course meta-information	enrollment histories	course grades	model type
bag-of-words	✓	✓				static
multi-c2v			✓	✓		dynamic
LSTM				✓		dynamic
sc-AMHEN				✓	✓	static

4.1 Bag-of-words

The basic representation mode of bag-of-words was proposed by information retrieval researchers for text corpora. It is a model that reduces each document in a corpus to a vector of real numbers, each of which represents a term, or vocabulary weight. The term weight can be term frequency, a binary value with 1 indicating that the term occurred in the document and 0 indicating that it did not, or a tf-idf scheme[7]. There are two sources of texts that can represent the content of courses: the course catalog descriptions and course syllabi.

4.2 Multifactor Course2vec

The Course2vec model [32] was proposed to learn distributed representations of courses from students' enrollment records throughout semesters by using a notion of an enrollment sequence as a "sentence" and courses within the sequence as "words", borrowing terminology from the natural language domain. For each student, their chronological course enrollment sequence is produced by first sorting by semester then randomly serializing within-semester course order. Each course enrollment sequence is then trained on like a sentence using a skip-gram model.

More features of courses (e.g., course instructor and department) can be added to the input of the multifactor Course2vec model to enhance the classifier and its representations. The model learns both course and added feature representations by maximizing the objective function over all the students' enrollment sequences and the features of courses, defined as follows.

$$\sum_{s \in S} \sum_{c_i \in s} \sum_{-w < j < w, j \neq 0} \log p(c_{i+j} | c_i, f_{i1}, f_{i2}, \dots, f_{ih}) \quad (1)$$

Probability $p(c_{i+j} | c_i, f_{i1}, f_{i2}, \dots, f_{ih})$ of observing a neighboring course c_{i+j} in window size w given the current course c_i and its features $f_{i1}, f_{i2}, \dots, f_{ih}$ (e.g., instructors, department) can also be defined via the softmax function,

$$p(c_{i+j} | c_i, f_{i1}, f_{i2}, \dots, f_{ih}) = \frac{\exp(\mathbf{a}_i^T \mathbf{v}'_{i+j})}{\sum_{k=1}^n \exp(\mathbf{a}_i^T \mathbf{v}'_k)} \quad (2)$$

$$\mathbf{a}_i = \mathbf{v}_i + \sum_{j=1}^h \mathbf{W}_{n_j \times v} \mathbf{f}_{ij} \quad (3)$$

where \mathbf{a}_i is the vector sum of input course vector representation \mathbf{v}_i and all the features vector representations of course c_i , \mathbf{f}_{ij} is the multi-hot input of the j -th feature of course i , and $\mathbf{W}_{n_j \times v}$ is the weight matrix for feature j . So by multiplying $\mathbf{W}_{n_j \times v}$ and \mathbf{f}_{ij} , it gets the sum of feature vector representations of the i -th course. The illustration of the model is shown in the multi-course part of Figure 2. \mathbf{v}_i is the course representation of course i learned from the model that is used in various down-stream course prediction tasks.

4.3 LSTM-learned Representations

In previous work [32], an LSTM was designed to recommend courses for students to take in the next semester, based on their enrollment histories. The input of the model in each time slice is a multi-hot vector representing the courses taken in the corresponding semester. The weights of the input \mathbf{W}_f , \mathbf{W}_i , \mathbf{W}_o , and \mathbf{W}_c learned by the LSTM transferred the

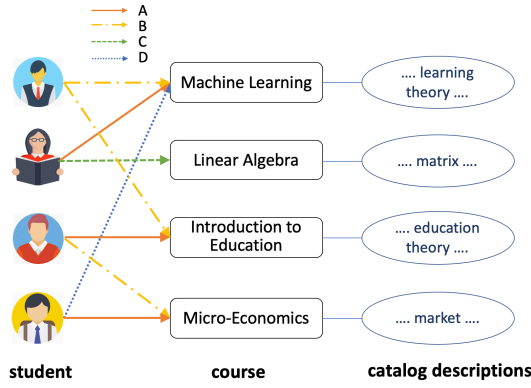

Figure 1: Illustration of the Attributed Multiplex Heterogeneous Network (AMHEN) of Students and Courses.

multi-hot input to the forget gate, input gate, output gate, and the cell in the LSTM cell, respectively. These four sets of weights are combined to form representations of courses that can be used in down-stream prediction tasks.

4.4 Attributed Multiplex Heterogeneous Network Embeddings

Network representation learning (i.e., network embedding), is a promising method to project nodes in a network onto a low-dimensional continuous space while preserving network structure and inherent properties. In terms of the network topology (homogeneous or heterogeneous) and attributed property (with or without attributes), six different types of networks can be categorized, i.e., HOMogeneous Network (HON) [34], Attributed HOMogeneous Network (AHON) [40], HETerogeneous Network (HEN) [9], Attributed HETerogeneous Network (AHEN) [5], Multiplex HETerogeneous Network (MHEN) [24], and Attributed Multiplex HETerogeneous Network (AMHEN) [4]. In the university setting, students and courses can be mapped into a large heterogeneous network, where students and courses are two types of nodes connected by students' enrollments in courses. The proximities between students and courses vary based on the grades (e.g., A, B, C, D, etc.) students received for courses, yielding the network with multiple views, i.e., multiplex heterogeneous network. Furthermore, if we incorporate the attributes of students and nodes (e.g., course catalog descriptions), the network will turn to an Attributed Multiplex HETerogeneous Network (AMHEN), which is illustrated in Figure 1. Because students may receive different grades for the courses they enrolled, we consider different grades as different edge types between students and courses.

DEFINITION 1. (*Attributed Multiplex Heterogeneous Network*): An attributed multiplex heterogeneous network is a network $G = (\mathcal{V}, \mathcal{E}, \mathcal{A})$, $\mathcal{E} = \cup_{r \in \mathcal{R}} \mathcal{E}_r$, where \mathcal{E}_r consists of all edges with edge type $r \in \mathcal{R}$, and $|\mathcal{R}| > 1$. We separate the network for every edge type $r \in \mathcal{R}$ as $G_r = (\mathcal{V}, \mathcal{E}_r, \mathcal{A})$. Each node $v_i \in \mathcal{V}$ is associated with some types of feature vectors. $A = \{x_i | v_i \in \mathcal{V}\}$ is the set of node features for all nodes, where x_i is the associated node feature of node v_i .

In the student-course attributed multiplex heterogeneous network we described above, $\mathcal{V} = (\mathcal{C}, \mathcal{S})$, where each node $c \in \mathcal{C}$ represents a course in the course set \mathcal{C} and each node $s \in \mathcal{S}$ represents a student in the student set \mathcal{S} . \mathcal{R} refers to all the edge types in the student-course attributed multiplex heterogeneous network, i.e., grade types. As students have enrollment and grade histories of multiple courses, we consider student embeddings as a state of their course knowledge. Different grade types mirror different levels of course knowledge, thus should be represented as different embeddings.

Given the above definitions and descriptions, we can formally define our problem for representation learning on the student-course AMHEN.

PROBLEM 1. (*Student-Course AMHEN Embedding*). Given a Student-Course AMHEN $G = (\mathcal{C}, \mathcal{S}, \mathcal{E}, \mathcal{A})$, the problem of Student-Course AMHEN embedding is to give a unified low-dimensional space representation of each student node $s \in \mathcal{S}$ and each course node $c \in \mathcal{C}$ on every grade type r . The goal is to find a function $g : \mathcal{S} \rightarrow \mathbb{R}^d$ and a function $f_r : \mathcal{C} \rightarrow \mathbb{R}^d$ for every grade (edge) type r , where $d \ll |\mathcal{C}|$ ($d \ll |\mathcal{S}|$).

4.4.1 Student and Course Representations

In this section, we detail our adaptation of the AMHEN framework[4] to the student-course scenario to learn graph-based student and course representations. We split the overall course embedding on each course type r into three parts: base embedding \mathbf{b}_c , grade embedding \mathbf{g} , and attribute embedding \mathbf{u} , and split the overall student embedding into two parts: base embedding \mathbf{b}_s , and individual embedding \mathbf{p} .

The base embedding of course node c_i , i.e., \mathbf{b}_{c_i} , is shared between different grade types. We define \mathbf{b}_{c_i} as a parameterized function of c_i 's attributes $\mathbf{x}_i \in \mathbb{R}^x$ as:

$$\mathbf{b}_{c_i} = h(\mathbf{x}_i) \quad (4)$$

where h is a transformation function, such as a multi-layer perceptron. The attribute embedding of course node c_i , i.e., \mathbf{u}_i , is defined as:

$$\mathbf{u}_i = D^T \mathbf{x}_i \quad (5)$$

Given that in the Student-Course AMHEN, the neighbors of a course are all students while the neighbors of students are all courses, the k -th level¹ of grade embedding $\mathbf{g}_{ir}^{(k)} \in \mathbb{R}^d$, ($1 \leq k \leq K$) of course node c_i on grade type r is aggregated from individual embeddings of students that are c_i 's neighbors, which means these students all received grade type r for course c_i .

$$\mathbf{g}_{ir}^{(k)} = \text{mean}(\{\mathbf{p}_j^{(k-1)}, \forall p_j \in \mathcal{N}_i\}) \quad (6)$$

Similarly, the k -th level of individual embedding $\mathbf{p}_i^{(k)} \in \mathbb{R}^d$, ($1 \leq k \leq K$) of a student node s_i is aggregated from grade embeddings of courses that are s_i 's neighbors, which demonstrates a student's representation is derived from the grade histories of his/her enrolled courses.

$$\mathbf{p}_i^{(k)} = \text{mean}(\{\mathbf{g}_{jr}^{(k-1)}, \forall c_j \in \mathcal{N}_i\}) \quad (7)$$

¹By level we mean iteration, i.e., the embedding is updated after each parameters update process.

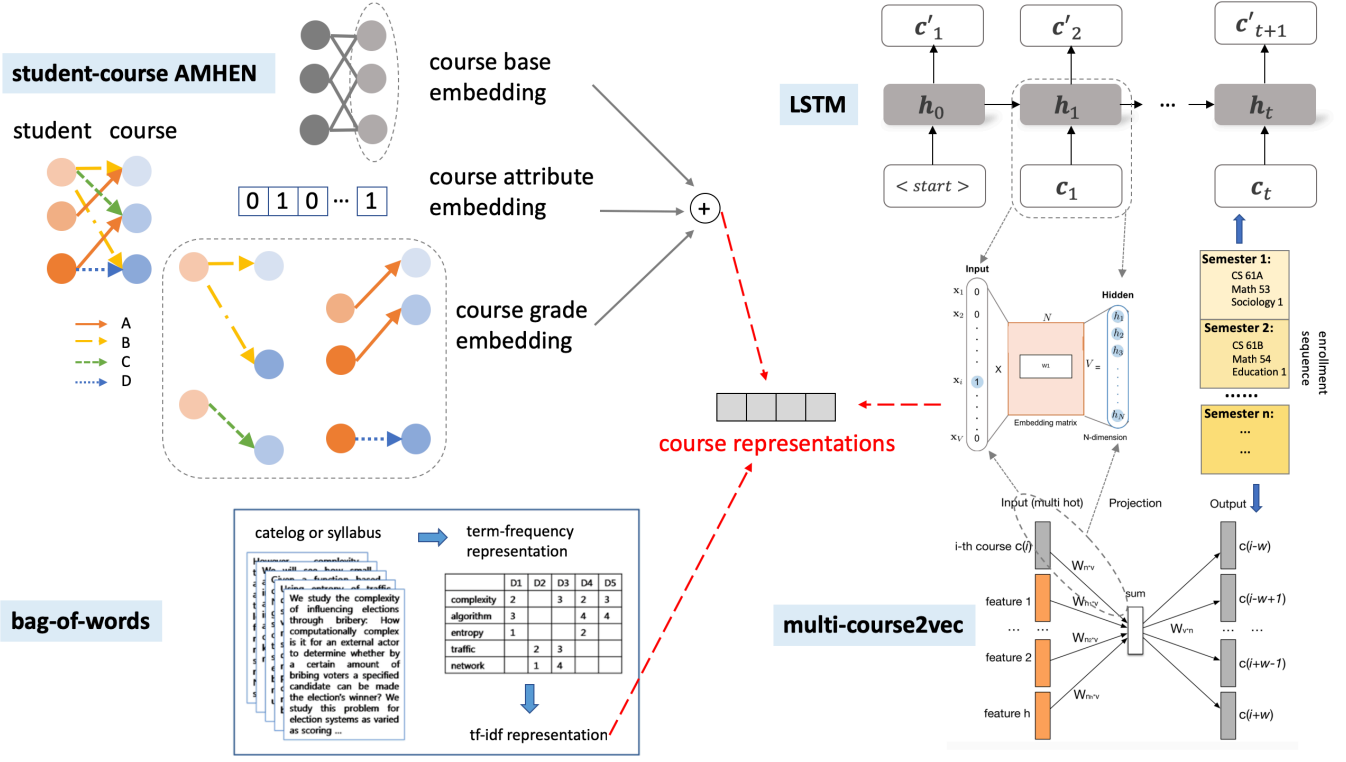

Figure 2: Visual summary of representation learning methods

We denote the k -th level grade embedding $\mathbf{g}_{ir}^{(k)}$ as grade embedding \mathbf{g}_{ir} , and concatenate all the grade embeddings for course node c_i as $\mathbf{G}_i \in \mathbb{R}^{d \times m}$, where d is the dimension of grade embeddings and m is the number of grade types.

$$\mathbf{G}_i = (\mathbf{g}_{i1}, \mathbf{g}_{i2}, \dots, \mathbf{g}_{im}) \quad (8)$$

We use self-attention mechanism[23] to compute the coefficients $\mathbf{a}_{ir} \in \mathbb{R}^m$ of linear combination of vectors in \mathbf{G}_i on edge type r as:

$$\mathbf{a}_{ir} = \text{softmax}(\mathbf{w}_r^T \tanh(\mathbf{W}_r \mathbf{G}_i))^T \quad (9)$$

where $\mathbf{w}_r \in \mathbb{R}^{d_a}$ and $\mathbf{W}_r \in \mathbb{R}^{d_a \times d}$ are trainable parameters for grade type r . Thus, the overall embedding of course node c_i for grade type r is:

$$\mathbf{c}_{ir} = \alpha_c h(\mathbf{x}_i) + \mathbf{M}_r^T \mathbf{G}_i \mathbf{a}_{ir} + \beta_c \mathbf{D}^T \mathbf{x}_i \quad (10)$$

where $\mathbf{M}_r \in \mathbb{R}^{d \times n}$ and $\mathbf{D} \in \mathbb{R}^{x \times n}$ are trainable transformation matrix. α_c and β_c are two coefficients adjusting the weights of the three embeddings of courses, which can also be trainable.

The overall embedding of student node s_i is:

$$\mathbf{s}_i = \alpha_s \mathbf{b}_s + \mathbf{N}^T \mathbf{p}_i \quad (11)$$

where α_s is a trainable coefficient adjusting the weights of the two embeddings of students, and $\mathbf{N} \in \mathbb{R}^{d \times n}$ is a trainable transformation matrix for the individual embeddings of students.

4.4.2 Model Optimization

Having the student and course representations constructed, we discuss how to generate the training data and learn the

student and course embeddings. We first separate the whole network by edge(grade) type, then given a view (grade type) r of the network, i.e., $\mathbf{G}_r = (\mathcal{C}, \mathcal{S}, \mathcal{E}_r, \mathcal{A})$, we use meta-path-based random walk[9] to generate node sequences. There are two meta-path schema in the student-course AMHEN, i.e., *student – course – student* or *course – student – course*. Finally, we apply a skip-gram [27, 28] over the node sequences to learn embeddings. The meta-path-based random walk strategy ensures that the semantic relationships between student nodes and course nodes with different grade types can be properly incorporated into the skip-gram model [9]. For a training pair (c_i, s_j) with grade type r , our objective is to maximize the probability:

$$P(s_j | c_i, r) = \frac{\exp(\mathbf{c}_{ir}^T \mathbf{s}_j')}{\sum_{s_k \in \mathcal{S}} \exp(\mathbf{c}_{ir}^T \mathbf{s}_k')} \quad (12)$$

where \mathbf{s}_k' is the context embedding of student node s_k . For a training pair (s_i, c_j) with grade type r , our objective is to maximize the probability:

$$P(c_j | s_i, r) = \frac{\exp(\mathbf{s}_i^T \mathbf{c}_{jr}')}{\sum_{c_k \in \mathcal{C}} \exp(\mathbf{s}_i^T \mathbf{c}_{kr}')} \quad (13)$$

where \mathbf{c}_{kr}' is the context embedding of course node c_k with grade type r . Finally, we use heterogeneous negative sampling to approximate the objective function $-\log P(s_j | c_i, r)$ for node pair (c_i, s_j) as

$$\text{loss}(c_i, s_j, r) = -\log \sigma(\mathbf{c}_{ir}^T \mathbf{s}_j') - \sum_{l=1}^L \mathbb{E}_{s_k \sim P(s_k)} [\log \sigma(-\mathbf{c}_{ir}^T \mathbf{s}_k')] \quad (14)$$

and the objective function $-\log P(c_j | s_i, r)$ for node pair (s_i, c_j) as:

$$\text{loss}(s_i, c_j, r) = -\log \sigma(\mathbf{s}_i^T \mathbf{c}'_{jr}) - \sum_{l=1}^L \mathbb{E}_{c_k \sim P(c_k)} [\log \sigma(-\mathbf{s}_i^T \mathbf{c}'_{kr})] \quad (15)$$

Here we define $P(s_k) = \frac{f(s_k)^{3/4}}{\sum_{i=1}^{|S|} f(s_i)^{3/4}}$ and $P(c_k) = \frac{f(c_k)^{3/4}}{\sum_{i=1}^{|C|} f(c_i)^{3/4}}$ according to the Skip-gram model[27], where f refers to the frequency of the node in each node type.

After optimizing the model with all the parameters learned, we reform the overall embedding for course i by concatenating its embeddings of all grade types.

$$\mathbf{c}_i = (\mathbf{c}_{i1}^T, \mathbf{c}_{i2}^T, \dots, \mathbf{c}_{im}^T)^T \quad (16)$$

5. TASKS

In this section, we describe five down-stream institutionally relevant tasks that can be performed by using the course representations constructed by the model approaches introduced in Section 4.

5.1 Course Similarity

An essential way to check the quality and fidelity of the course representations introduced in section 4 is to test whether they contain important features of courses that could differentiate between similar and dissimilar courses. To this end, an equivalency validation set of 1,351 course credit-equivalency pairs maintained by the Office of the Registrar were used for similarity based ground truth. A course is paired with another course in this set if a student can only receive credit for taking one of the courses at the university. For example, an honors and non-honors version of the same course will appear as a pair because faculty have deemed that there is too much overlapping material between the two for a student to receive credit for both.

To evaluate different course representations on the course equivalency validation set, we fixed the first course in each pair and ranked all the other courses according to their cosine similarity to the first course in descending order. We then noted the rank of the expected second course in the pair and describe the performance of each model on all validation pairs in terms of Mean Rank, Median Rank and Recall@10.

5.2 Enrollment Prediction

Enrollment prediction involves predicting the courses a student will enroll in, but not the grade they will receive. For this reason, it is considered a model of behavior, rather than an assessment model. The task could be potentially useful for the purpose of providing a normative course taking signal that could be used to provide a personalized sorting of course results (e.g., showing the courses a student is most likely to take that satisfy a remaining requirement) [32]. The input of the model in each time slice is a multi-hot vector representing the courses taken in the corresponding semester. However, the multi-hot representation has a large dimension of total number of courses and may not encode course features apparent in text descriptions of the course or graph-based methods. Therefore, we also evaluate substituting the multi-hot course input with the sum of pre-trained low-dimensional representations from other models, illustrated

in Figure 3. Performance on this task is reported in terms of Recall@10 and Mean Reciprocal Rank@10 (MRR@10). MRR evaluates recommender system models that produce a list of ranked items for queries. The reciprocal rank is the “multiplicative inverse” of the rank of the first correct item. MRR is defined as $\text{MRR} = \frac{1}{|Q|} \sum_{i=1}^Q \frac{1}{\text{rank}_i}$, where rank_i represents the rank of the first correct recommended item for query i . For calculating MRR@10, the only difference is rank_i is reset to 0 if $\text{rank}_i > 10$.

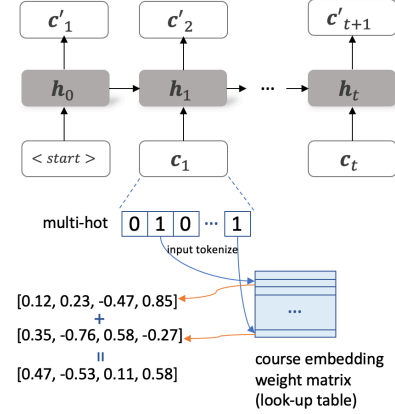

Figure 3: Illustration of the LSTM-based next-course prediction

5.3 Grade Prediction

Grade prediction is the basis for an assessment model that could aid adaptive sequencing of courses to achieve a particular goal. In previous work[21], a modified LSTM was designed to trace students’ course knowledge, which predicted students’ grades on enrolled courses in each semester. The model gives students the ability to choose their grade goal (A or B) or Pass/No-pass. A masked loss function was designed to enable the output to predict letter grade and Pass/No-pass independently. Two cut-offs (A or B) were also set to separate the letter grades into two levels (e.g., higher and lower than an ‘A’). The input of the LSTM grade prediction model is also a multi-hot vector with the position of grades students received for enrolled courses as 1 and other positions as 0. Because there are seven grade types for each course, the dimensions of the model input in each time slice is the number of courses multiplied by seven. As an alternative to the multi-hot input, we also evaluate the performance of the model using the course grade representations learned from the student-course AMHEN model in Section 4.4, which is illustrated in Figure 4, where \mathbf{g}_i represents the grades of courses taken in semester i and \mathbf{c}_i represents the courses taken in semester i . \mathbf{c}_{i+1} is concatenated with \mathbf{g}_i to incorporate the impact of the co-enrolling effect of courses in the predicted semester on grade prediction.

In addition, the student-course AMHEN model can also predict the grades of students by calculating the cosine similarities between student embeddings and course embeddings, and then predicting the grades by picking up the grade of each course that is most similar to the target student.

$$g(s_i, c_j) = \arg \max_r \cos(\mathbf{s}_i, \mathbf{c}_{jr}) \quad (17)$$

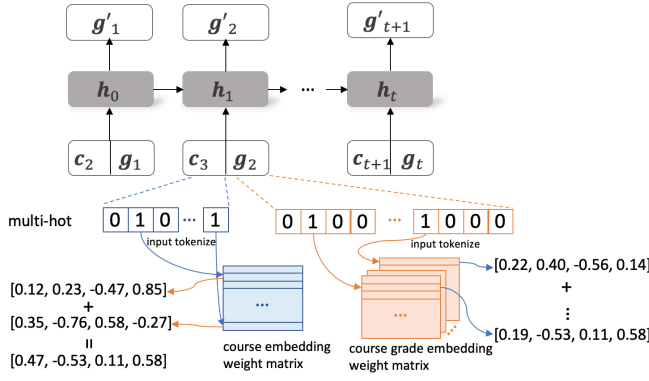

Figure 4: Illustration of the LSTM-based grade prediction

For the model without grade cut-off, there are seven grade types in the student-course AMHEN model representing A, B, C, D, F, Pass, and No-pass. A prediction is considered correct only if it is exactly the grade a student received in the data. For the models with grade cut-off (A or B), we group the letter grades not lower than the cut-off as a grade type, and the letter grades lower than the cut-off as another grade type in the student-course AMHEN model.

Both the enrollment prediction and grade prediction models were trained using a temporal train/test split, with Fall 2008 through Fall 2015 semesters serving as the training set and Spring 2016 as the testing semester.

5.4 Prerequisite prediction

Prerequisite course information is essential to encourage or mandate that students have the necessary foundational experience to be able to learn and succeed in the advanced stages of their degree. We used a set of 2,300 prerequisite course pairs, provided by the UC Berkeley Office of the Registrar, which contains 1,215 target courses, as a source of ground truth to test whether the grade prediction model encodes such prerequisite relationships between courses.

Prerequisite relationships between courses can be inferred by inferring an LSTM-based grade prediction model as described in [21] and illustrated in Figure 5. Note that, for this evaluation, only one time slice input of the binary-grade (A or lower than A) prediction trained LSTM is needed. We iterate over all the courses with only one-hot embedded in the ‘A’ position for that course, and feed the input, which is a concatenation of a target course and grade A of the input course, to the LSTM. During the iterations, the input course that boosted the probability of the ‘A’ position of target course to the largest ten values will be selected as candidate prerequisite courses for the target course. This approach is similar to the prerequisite skill inference conducted with DKT [35], but with a much larger vocabulary and with ground truth prerequisite structure to validate against. As with the other tasks, we also evaluate replacing the input of this model with representations from the student-course AMHEN graph-embedding approach.

A simple multinomial logistic regression can alternatively be

used to predict prerequisites courses using any arbitrary vector representation of a course. The input of the multinomial logistic regression during training is the vector representation of the target course, and the output is a multi-hot of the prerequisite courses for the target course. During testing, the output is a probability distribution across all courses where the most probable courses can be taken as the prerequisite predictions of the regression.

We classified all the models for the prerequisite course prediction task into two types, supervised and unsupervised, based on whether the model was learned using the official prerequisite course pairs. For the supervised models (i.e., using the regression), we applied 10-fold cross-validation to the 2,300 prerequisite course pairs. For the unsupervised models (i.e., LSTM-based inferences), described in Section 5.4, the LSTM with standard course multi-hots as input and with graph-based embeddings as input was trained first on the supervised task of predicting course grades, and was then inferred in an unsupervised manner (i.e., not using any prerequisite ground truth), to predict course prerequisites.

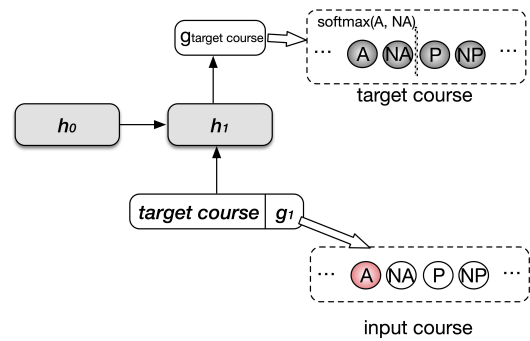

Figure 5: Prerequisite course prediction using LSTM-based grade prediction model[21]

5.5 Average Enrollment Prediction

Do the representations of courses created by various modeling techniques encode course popularity information? To answer this we test the course representations’ ability to predict the average enrollment size of each course. The data and models that perform well in this test may be indicative of the data and modeling paradigms that would work well for temporal versions of this model that could anticipate increases in course demand and allow institutions to better plan room and teaching staff allocations.

In order to check whether the different types of course embeddings encode information predictive of the number of enrollments, we use a simple a multi-layer perceptron to predict average enrollment per course using the different types of course embeddings introduced in section 4 as candidate inputs. RMSE is adopted as the error metric.

6. EXPERIMENT RESULTS

We begin this section by reporting a summary of only the best performing model and data source pairs used to construct the input representations for each of our five downstream model predictions tasks. This summarized set of best

Table 3: Evaluation of course representation models on various prediction tasks

Representation created by		Course similarity prediction		Enrollment prediction		Grade prediction	Prerequisite prediction		Avg-enroll-predict
Model	Data Source(s)	Mean/ Median Rank	Recall@10	Recall@10	MRR@10	Accuracy	Recall@10	Target	RMSE
bag-of-words	catalog	602/6 ^[33]	0.5370 ^[33]	0.3154	0.5216	-	0.5152	0.5938	42.4781
bag-of-words	syllabus	329/19	0.4270	0.3744	0.5103	-	0.5658	0.6352	48.8965
multi-c2v	enrollments, course meta-information	224/15 ^[33]	0.4485 ^[33]	0.3791	0.5576	-	0.6957	0.7733	42.4780
LSTM (multi-hot)	enrollments	584/58	0.2924	0.3967	0.5885	0.6952	0.3048 ^[21]	0.4486 ^[21]	51.4140
sc-AMHEN	enrollments, grades, catalog	288/11	0.4767	0.3882	0.5625	0.7008	0.7192	0.8000	52.3370

results are shown in Table 3. On the task of course similarity, a simple bag-of-words representation of the course catalog description performs best in terms of median rank and Recall @ 10 on our credit-equivalency pairs validation set. Enrollment histories provide the second best performing score using sc-AMHEN network-based embedding, followed by multi-c2v. Scoring similarly to multi-c2v was a simple BOW of the lms-syllabus data. On the task of predicting which courses a student will take next (enrollment prediction), an LSTM with a multi-hot input representation of courses taken in each semester provided the best performance in terms of both metrics. In this task, using pre-trained embeddings from the network-based or multi-c2v approach worked less well than multi-hot, followed by using the content-based representations as inputs, which performed worst. In grade prediction, the network-based method performed slightly better than the previous state-of-the-art LSTM. On the task of prerequisite prediction, the network-based approach performed best in recovering the ground-truth prerequisite relationships found in our institutional data. The multi-c2v approach was not far behind. The content-based and LSTM course representations did not perform nearly as well on this task. Finally, on the task of predicting the average enrollment of a course, multi-c2v provided the lowest RMSE, but with an almost identical score achieved by simple BOW of the course catalog description.

In the subsequent sections we provide a more detailed breakdown of performance of all model and data combinations on the tasks of course similarity, grade prediction, and prerequisite prediction. Results of enrollment prediction and average enrollment prediction are already shown in full in Table 3.

6.1 Course Similarity

The evaluation results on the equivalency validation set of 1,351 course credit-equivalency pairs are shown in Table 4. The bag-of-words representations (Tf-idf) generated from course catalog descriptions achieved better median rank and recall@10 than those generated from the course syllabus data. However, the mean rank of the catalog-based representations is the worst among all the models, which suggests there are many outliers where literal semantic similarity (bag-of-words) is very poor at identifying equivalent pairs. Concatenations of the bag-of-words based methods and course2vec-based method increased the evaluation met-

Table 4: Course similarity validation of all the course representations

Model	Mean/Median Rank	Recall @10
catalog	602/6	0.5372
syllabus	329/19	0.4270
course2vec (c2v)	244/21	0.3839
multi-c2v (mc2v)	224/15	0.4485
catalog+mc2v	132/3	0.6435
syllabus+mc2v	109/6	0.5798
catalog+syllabus+mc2v	79/3	0.6705
catalog+syllabus+mc2v (PCA dim: 300)	177/3	0.6544
LSTM	584/58	0.2924
sc-AMHEN(<i>u</i>)	288/11	0.4767
sc-AMHEN(<i>c</i>)	330/27	0.3603

rics, especially when the bag-of-words representations of catalog and syllabus were combined with the multi-factor course2vec representations, reaching a mean/median rank of 79/3 and recall@10 of 0.6705, the best among all the models. A Principal Component Analysis (PCA) transformation of the concatenated course vectors from 10,000 to 300 did not diminish the median rank metric, but slightly negatively affected average rank and recall. The course representations learned from the next-course prediction LSTM performed the worst among all the models. Course attribute embeddings sourced from the student-course AMHEN (sc-AMHEN) model, performed second best among all single representation models.

6.2 Grade Prediction

The *accuracy* of the grade predictions generated by the pure student-course AMHEN model (sc-AMHEN(*s, c*)), the LSTM model with multi-hot as input (LSTM(multi-hot)), and the LSTM model with course embeddings with different grade types (LSTM(*u, c*)) are listed in Table 5. Among the three models, the pure student-course AMHEN model is a kind of static model learned from students' enrollment data with grades and course catalog descriptions, while the two LSTM-based models are dynamic models taking into consideration not only the student enrollment data with grades, but also the sequential information (semester order) of the grades of enrolled courses. The grade prediction results show that the graph model, though static, could map the knowledge

Table 5: Grade prediction evaluation (accuracy)

Model	Type	Cut-off	Letter grade	Pass/No-pass	All
sc-AMHEN (\mathbf{s}, \mathbf{c})	static	-	0.5441	0.7972	0.5976
LSTM (multi-hot)	dynamic	-	0.6382	0.9079	0.6952
LSTM (\mathbf{u}, \mathbf{c})	dynamic	-	0.6418	0.9209	0.7008
sc-AMHEN (\mathbf{s}, \mathbf{c})	static	A	0.5526	0.7791	0.6004
LSTM (multi-hot)	dynamic	A	0.7523	0.8581	0.7633
LSTM (\mathbf{u}, \mathbf{c})	dynamic	A	0.7571	0.9135	0.7902
sc-AMHEN (\mathbf{s}, \mathbf{c})	static	B	0.8299	0.8205	0.8279
LSTM (multi-hot)	dynamic	B	0.8805	0.9178	0.8884
LSTM (\mathbf{u}, \mathbf{c})	dynamic	B	0.8817	0.9185	0.8895

levels of students on the features of courses with different grade types to a certain degree, resulting in prediction accuracies higher than 0.5 for all grade types and higher than 0.6 and 0.8 for binary grades (“not lower than cut-off” v.s. “lower than cut-off”, Pass v.s. No-pass) on average. Furthermore, the sequential information of students’ grades by semesters exhibited substantial importance as the prediction accuracy of the two LSTM-based models manifested superiority to the static student-course AMHEN model by a significant margin. Moreover, the course embeddings with different grade types learned from the student-course AMHEN model helped increase the accuracy of grade prediction over the multi-hot vectors as the input of the LSTM. The potential reasons could be the course embeddings with different grade types captured the knowledge relations among grades of a course and the relations among different courses, thus could represent the knowledge of students more accurately than multi-hot, which could not encode any knowledge relations among grades. Although the positive impact of incorporating grade embeddings on grade prediction (improvement at the 0.01 level) are not so salient as the advantage of bringing in sequential information (improvement at the 0.1 level), it is manifested in all the evaluations with different grade types.

6.3 Prerequisite prediction

The evaluation results of prerequisite course prediction are shown in Table 6. The supervised models performed dramati-

Table 6: Prerequisite course prediction

Model	Supervised	Pairs (Recall@10)	Target course
LSTM(one-hot)	X	0.3048	0.4486
LSTM(\mathbf{u}, \mathbf{c})	X	0.2423	0.3580
catalog	✓	0.5152	0.5938
syllabus	✓	0.5658	0.6352
mc2v	✓	0.6957	0.7733
sc-AMHEN(\mathbf{u}, \mathbf{c})	✓	0.7192	0.8000

cally better in reconstructing the prerequisite pairs. Among all types of course representations, the course embeddings and grade embeddings learned from the student-course AMHEN performed the best, reaching 71.92% of the prerequisite pairs

correctly predicted and 80% of all the target courses with at least one of their prerequisite course correctly predicted. For unsupervised models, we found one-hot representation of courses performed better than course and grade embeddings in the prerequisite course inference framework described in Section 5.4.

7. CONCLUSIONS

In this paper, we evaluated the utility of two content-sources of data about courses, catalog descriptions and syllabi, as well as enrollment histories and grades. We paired these sources with four different representations produced by simple bag-of-words, multifactor Course2vec, LSTM, and network-based embedding. We compared the performance of these pairings on five prediction tasks, course similarity, enrollment prediction, grade prediction, prerequisite prediction, and average enrollment prediction.

On the topic of the utility of syllabus data, which has not been evaluated before, we found that it showed benefit over catalog description data only in inferring prerequisite relationships (Recall of 0.5658 vs 0.5152), perhaps due to syllabi being the finer-grained source of content information about a course. In terms of course similarity signal, catalog description was markedly better than syllabus (Recall of 0.5372 vs 0.427) and our results indicate that catalog description, syllabus, and enrollment histories all bring some level of complementary information as the combination of all three performed better than any one or two combined. Enrollment data was used in the best scoring model in four of the five tasks, with only the best performing course similarity task model not utilizing enrollments. The nascent network-based approach performed well on all tasks, and was the top model in grade prediction and prerequisite prediction.

To conclude: (1) syllabus data is worth the effort to collect compared to catalog description for prerequisite prediction and (2) complements the catalog description and enrollment data on the course similarity task, (3) for prerequisite learning, supervised approaches based on embeddings perform much better than inferencing a pre-trained assessment model, (4) multifactor Course2vec often performs close to the more complex network-based approach on all tasks and (5) seeding the LSTM with course representations from the other models did not improve next-course prediction performance, while seeding with course grade representations from the student-course AMHEN model provided a small improvement in the grade prediction task.

8. LIMITATIONS AND FUTURE WORK

Our analyses were limited to data from a single large public institution in the US. Future work will need to evaluate multiple institutions of varying sizes, student demographics, and course taking policies in order to examine the generalizability of these approaches. In terms of models, we focused on simple text-based approaches and more complex neural models, both well established and nascent. Classical models of intermediary complexity were not evaluated.

We included tasks that have been common in EDM papers involving enrollment data; however, other institutional tasks exist that could be evaluated to produce an even more comprehensive analysis. These tasks include course preparation

recommendation [21, 20], degree or course attrition prediction, and future course demand forecasting.

Syllabi in their original form could be evaluated, instead of in bag-of-words form, in order to investigate if the positionality of words in the syllabi offered any additional predictive utility. Lastly, learning management system clickstream data, as well as content information in addition to the syllabus, could be leveraged to enhance both content-based and collaborative-based course representations. This combination of different modalities and scales of data is an identified open challenge for the field [14].

9. ACKNOWLEDGEMENTS

We would like to thank Sandeep Jayaprakash and Oliver Heyer from UC Berkeley’s Research Teaching, and Learning for supporting this research by facilitating the limited use of course syllabus data as pre-processed bag-of-words. We also thank the UC Berkeley Office of the Registrar for providing anonymized student enrollment data and access to course information APIs.

Pick the Moment: Identifying Critical Pedagogical Decisions Using Long-Short Term Rewards

ABSTRACT

Identifying critical decisions is one of the most challenging decision-making problems in real-world applications. In this work, we propose a novel Reinforcement Learning (RL) based Long-Short Term Rewards (LSTR) framework for critical decisions identification. RL is a machine learning area concerning with inducing effective decision-making policies, following which result in the maximum cumulative *reward*. Many RL algorithms find the optimal policy via estimating the optimal *Q-values*, which specify the maximum cumulative reward the agent can receive. In our LSTR framework, the *long term* rewards are defined as *Q-values* and the *short term* rewards are determined by the *reward function*. Experiments on a synthetic GridWorld game and real-world Intelligent Tutoring System datasets show that the proposed LSTR framework indeed identifies the critical decisions in the sequences. Furthermore, our results show that carrying out the critical decisions alone is as effective as a fully-executed policy.

Critical Decisions, Pedagogical Strategies, Critical Reinforcement Learning, Reinforcement Learning

1. INTRODUCTION

People make decisions every day, from minor decisions such as what to eat for lunch, to major decisions such as which college to enroll. This is equally true for tutorial interactions. Some decisions, such as what type of example to use may be minor, while others such as whether to give a new problem, or provide a solution for an old one, may not. In many cases the true significance of these decisions will not be known until well after the fact (much delayed), when students' exam scores come in or beyond. Moreover, for many such decisions, the significance is often individualized. So our research question is: *Given a long trajectory of decisions, can we automatically identify those which are critical to the outcome?*

Song Ju, Min Chi and Guojing Zhou "Pick the Moment: Identifying Critical Pedagogical Decisions Using Long-Short Term Rewards" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 126 - 136

Our work is primary concerned with identifying critical decisions in interactive learning environments such as Intelligent Tutoring Systems (ITSs) and educational games, where the human-agent interactions can be viewed as a temporal sequence of steps [2, 14]. Most ITSs are *tutor-driven* in that *the tutor* decides what to do next. For example, the tutor can *elicit* the subsequent step from the student either with prompting or without (e.g., in a free form entry window where each equation is a step). When a student enters an entry on a step, the ITS records its success or failure and may give feedback (e.g. correct/incorrect markings) and/or hints (suggestions for what to do next). Alternatively, the tutor can choose to *tell* them the next step directly. Each of such decisions affects the student's successive actions and performance and some may be more impactful than others. *Pedagogical policies* are used for the agent (tutor) to decide what action to take next in the face of alternatives.

Reinforcement Learning (RL) offers one of the most promising approaches to data-driven decision-making for improving student learning in ITSs. RL algorithms are designed to induce effective policies that determine the best action for an agent to take in any given situation so as to maximize a cumulative reward. In recent years, RL, especially Deep RL, has achieved superhuman performance in several complex games [25, 26, 3]. However, different from the classic game-play situations where the ultimate goal is to make the agent effective, in human-centric tasks such as ITSs, the ultimate goal is for the agent to make the *student-system interactions* productive and fruitful. A number of researchers have studied the application of existing RL algorithms to improve the effectiveness of ITSs [5, 24, 16, 21, 20, 19, 6, 27, 10, 31, 30, 32]. While promising, relatively little work has been done to analyze, interpret, explain, or generalize RL-induced policies. While traditional hypothesis-driven, cause-and-effect approaches offer clear conceptual and causal insights that can be evaluated and interpreted, RL-induced policies are often large, cumbersome, and difficult to understand. The space of possible policies is exponential in the number of domain features. It is therefore difficult to identify the system decisions that critical to desirable outcomes. This raises a major open question: *How can we identify the critical system interactive decisions that are linked to student learning?*

In this work, we propose Long-Short Term Rewards (LSTR) framework to identify *critical* decisions based on RL-induced policy. For RL-induced policies, we explore Deep Q-Networks (DQNs) [18] and also modify Deep Q-Networks based on

critical decisions referred as Critical DQN in the following. More specifically, we define critical decisions as those optimal decisions have to be made for the desired outcomes. To quantify their impacts, we define critical policy as the one which will carry out the optimal actions on the critical decisions while randomly on others. To identify critical decisions, we investigate on using an RL-induced policy's action-value functions (long term) alone and using both action-value functions (long term) and immediate rewards (short-term). The effectiveness of the proposed LSTR framework is evaluated on a synthetic GridWorld game and real-world Intelligent Tutoring System datasets. Our results show that the proposed LSTR framework indeed identifies critical decisions and moreover, carrying out the critical decisions alone is as effective as a fully-executed policy.

Our main contributions are summarized as follows: 1) we proposed the Long Short Term Rewards framework to identify critical decisions and evaluated on both a synthetic GridWorld game and real-world ITS dataset. 2) we proposed Critical DQN to improve the long term rewards in identifying critical decisions and investigated its advantages and disadvantages.

2. METHOD

We follow the conventional Reinforcement Learning (RL) notation. An agent interacts with an environment over a series of decision-making steps. The environment is framed as a Markov Decision Process (MDP). At each timestep t , the agent observes the state the environment is in, denoted s_t ; then the agent chooses an action from a discrete set of possible actions: $A \in (a_1, a_2, \dots, a_n)$. As a result, the environment provides a scalar *immediate reward* r . We assume that the future rewards are discounted by the factor $\gamma \in (0, 1]$, and the agent's goal is to maximize the expected discounted sum of future rewards, also known as the return. The return at time-step t is defined as $R_t = \sum_{t'=t}^T \gamma^{t'-t} r_{t'}$, where T is the last time-step in the episode.

The goal of the agent is to find the optimal action-value function $Q^*(s, a)$, which will result in the agent receiving the highest possible expected return, starting from state s , taking action a , and following the optimal policy π^* thereafter. Formally, we define the optimal action-value function as $Q^*(s, a) = \max_{\pi} \mathbb{E}[R_t | s_t = s, a_t = a, \pi]$. The optimal action-value function must follow the *Bellman Equation* shown in Equation 1, which states that the Q-value for a given state and action should be equal to the immediate reward obtained after taking that action, plus the discounted Q-value of the optimal action a' taken from the next state s' . Note that this is an expectation over the next states sampled from the environment.

$$Q^*(s, a) = \mathbb{E}_{s' \sim \mathcal{E}} [r + \gamma \max_{a'} Q^*(s', a') | s, a] \quad (1)$$

In our case, we follow the batch Reinforcement Learning formulation in that we have a fixed-size dataset \mathcal{D} consisting of all historical sample episodes and each episode is denoted as $s_1 \xrightarrow{a_1, r_1} s_2 \xrightarrow{a_2, r_2} s_3 \xrightarrow{a_3, r_3} \dots s_L$. To make this task more general, we assume that the state distribution and behavior policy that were used to collect this data are both unknown.

In the following, we will describe the two DRL algorithms explored: DQN and Critical DQN and two ways of defining critical decisions: long term reward vs. long-short term reward. Based on two types of DRL methods and two ways of identifying critical decisions, we will compare six different policies.

2.1 Two Types of Deep RL Policy

2.1.1 Original DQN

Deep Q-Network (DQN) is one of most promising approaches which is widely used on areas like robotics and video games [18]. Fundamentally, DQN is a version of Q-learning which uses neural networks to approximate the Q-values of the different state-action couples. In order to train the DQN algorithm, the two neural networks with equal architectures are employed: one for calculating the Q-value of the current state and action: $Q(s, a)$ and another neural network to calculate the Q-value of the next state and action: $Q(s', a')$. The former is the main network and its weights are denoted by θ and the latter is the target network, and its weights are denoted by θ^- . The *Bellman Equation* for DQN is shown in Equation 2 and it is trained through running a gradient descent algorithm to minimize the squared difference of the two sides of the equality.

$$Q(s, a; \theta) = \mathbb{E}_{s' \sim \mathcal{E}} [r + \gamma \max_{a'} Q(s', a'; \theta^-)] \quad (2)$$

The main network is trained on every training iteration, while the target network is frozen for a number of training iterations. Every k training iterations, the weights of the main neural network are copied into the target network. This is one of the techniques used in order to avoid divergence during the training process. In practice, DQN also uses an experience replay buffer to store the recently collected data and to uniformly sample (s, a, r, s') steps from it. By sampling uniformly, it breaks the correlations between samples of the same episode, making the learning process more robust and stable. In this work, as we are doing batch RL, our whole dataset will be the experience replay buffer, and it will not change during the training process.

Basically, DQN is a Q-learning method that it finds the optimal action-value function by updating its action-value function approximator recursively. Its major difference from the traditional RL is that a deep neural network is used as action-value function approximator and this allows it to deal with the tasks with high dimensional state space.

2.1.2 Critical DQN

In the original DQN, the Q functions are estimated based on the assumption that the optimal policy will be followed to the end. We define *critical policy* to be the one that the optimal decision will be carried out on critical decision points while random decisions on the rest. By not taking the optimal actions on non-critical decisions, we fundamentally change the dynamics of Bellman equation which assumed full-execution of the policy. Therefore we need to modify it so that it can incorporate our critical decisions into consideration.

For a single (s, a, r, s') tuple, the original Bellman Equation can be expressed as:

$$Q(s, a) = r + \gamma \max_{a'} Q(s', a') \quad (3)$$

where r is the immediate reward for taking action a at state s ; γ is the discount factor; and $Q(s', a')$ is the action-value function for taking action a' at the subsequent state s' .

To induce a critical policy, we will modify the original Bellman equation based on whether a decision is critical or not. The intuition behind the Critical DQN is that if a decision is important, then the agent should take the best action otherwise the agent can randomly choose an action to take. Therefore, we have:

$$Q(s, a) = \begin{cases} r + \gamma \max Q(s', a') & s' \text{ is critical} \\ r + \gamma \text{mean} Q(s', a') & s' \text{ is non-critical} \end{cases} \quad (4)$$

In equation 4, to update the Q-value for any given s and a , it will consider whether the next state s' is critical or not. If it is critical, the maximum Q-value for s' will be used to update $Q(s, a)$; if the decision s' is non-critical, then the average Q-value among all the actions on s' will be used to update $Q(s, a)$.

Algorithm 1 presents the pseudo-code for critical DQN. First, it initializes all Q-values using the immediate rewards to avoid the bias of the neural network. In the main training loop, for each iteration, the algorithm first calculate the median threshold of Q-value difference over all the states. Then, for each (s, a, r, s') tuple, if the Q-value difference of s' is larger than the median threshold, we consider the decision on that state is critical and its value function is $\max_{a'} Q(s', a'; \theta^-)$; for non-critical decisions, their value function are defined as $\text{mean}_{a'} Q(s', a'; \theta^-)$. In this work, we assumes that half of the decisions in the training dataset are critical so that the median threshold is applied to separate critical and non-critical decisions quantitatively.

2.2 Two Types of Critical Rewards

2.2.1 Long Term Rewards (LongTRs)

In RL, $Q(s, a)$ is an estimation of the cumulative future rewards the agent will receive by taking action a at state s and following the policy to the end. If the Q-values for all the actions are the same, then it doesn't matter which action to take because all the actions will result in the same final reward. If the Q-value for one action is much larger than the others, then taking that action will have great impact on the future reward and this decision should be critical. So, the Long Term Reward is defined as how much cumulative future rewards the best action will obtain compared with the worst action. For this paper, we therefore define the Long Term Reward (LongTR) as:

$$\text{LongTR}(s) = \max_a Q(s, a) - \min_a Q(s, a) \quad (5)$$

which is the difference between the maximum and minimum Q-values in the state s . In general, the higher the LongTR, the more important the decision is.

Algorithm 1 Pseudocode of Critical DQN

```

1: Initialize the training dataset  $D$  as  $(s, a, r, s')$  tuples.
2: Initialize the Q function with random parameters  $\theta$ 
3: Initialize the target  $\hat{Q}$  function with parameters  $\theta^- = \theta$ 
4:
5: // Initialize  $Q(s, a)$  as immediate reward
6: for each  $(s_i, a_i, r_i, s'_i)$  in  $D$  do
7:   set  $y_i = r_i$ 
8: end for
9: Perform gradient descent on  $(y_i - Q(s_i, a_i; \theta))^2$ 
10: Reset  $\hat{Q} = Q$ 
11:
12: // Main Training Loop
13: for iteration  $k = 1, 2, \dots$  till convergence do
14:   Initialize empty array  $Q_{diffs}$ 
15:   for each  $(s_i, a_i, r_i, s'_i)$  in  $D$  do
16:      $Q_{diffs} \leftarrow (\max Q(s_i, a'; \theta^-) - \min Q(s_i, a'; \theta^-))$ 
17:   end for
18:    $\text{median\_threshold} = \text{median}(Q_{diffs})$ 
19:   for each  $(s_i, a_i, r_i, s'_i)$  in  $D$  do
20:     if terminal  $s'_i$  then
21:       Set  $y_i = r_i$ 
22:     else
23:        $Q_{diff} = \max Q(s'_i, a'; \theta^-) - \min Q(s'_i, a'; \theta^-)$ 
24:       if  $Q_{diff} > \text{median\_threshold}$  then
25:         Set  $y_i = r_i + \gamma \max_{a'} Q(s', a'; \theta^-)$ 
26:       else
27:         Set  $y_i = r_i + \gamma \text{mean}_{a'} Q(s', a'; \theta^-)$ 
28:       end if
29:     end if
30:   end for
31:   Perform gradient descent on  $(y_i - Q(s_i, a_i; \theta))^2$ 
32:   Every  $C$  steps reset  $\hat{Q} = Q$ 
33: end for

```

2.2.2 Long-Short Term Rewards (LSTRs)

For the LongTR, it only considers the cumulative future rewards but not immediate rewards. In a deterministic environment, LongTR is enough to identify critical decisions. But in a stochastic environment like the real world, some non-critical decision points would become critical and the LongTR can't detect their importance. For example, Figure 1 shows a simple MDP with seven states and one reward in the central state. Based on the LongTR, the decisions on S2 and S3 are critical because if doesn't move to the center, the agent will miss the +10 rewards. S1 is not critical based on LongTR because either move up or down doesn't affect collecting the reward as long as the agent takes the right action on state S2 or S3. However, in a stochastic environment, the agent should get the reward as soon as possible because the longer the path, the higher the risk to deorbit the rail. In RL, the LongTR can't learn the importance of state S1 but the immediate reward can. So, immediate rewards are served as Short Term Rewards (ShortTRs) in LSTR to complement the weakness of LongTRs that the agent should collect the rewards immediately without wandering.

2.3 Identifying & Evaluating Critical Decision

The effectiveness of our LSTR framework on identifying critical decisions is evaluated by the performance of **critical policy**. Unlike normal RL policies whose decisions are car-

Figure 1: An MDP Example for LSTR

ried out all the time, our critical policy only follows the RL policy’s decisions at critical points and takes random actions otherwise. Ideally, the more accurate the critical decisions are identified, the better performance the critical policy should have.

More specifically, for a given training data set, we can induce RL policies following the original DQN or the Critical DQN, named as π or π_c , respectively. For each of the policy, there are two ways to identify critical decisions, using LongTR (L) and using LSTR (LS). Based on the rewards used for critical decision identification and the policy used for execution, we have the following six critical policies shown in the table 1.

Table 1: Six Critical Policies

	Critical Policy	Execution Policy	Rewards for Identifying Critical Decision
1	$\pi(L)$	π	LongTRs in π
2	$\pi(LS)$	π	LSTRs in π
3	$\pi_c(L_c)$	π_c	LongTRs in π_c
4	$\pi_c(LS_c)$	π_c	LSTRs in π_c
5	$\pi(L_c)$	π	LongTRs in π_c
6	$\pi(LS_c)$	π	LongTRs in π_c

The first four critical policies are a simple 2 (π vs. π_c) by 2 (L vs. LS) combination that each policy uses its own rewards to identify critical decisions. However, the connection between the critical decisions and the performance of critical policy is based on the assumption that the policy carried out at the critical points are optimal. In the Critical DQN, average Q-value is considered in the updating process and this may slow down the convergence. As a result, the policy π_c can be non-optimal. So, we include other two critical policies: $\pi(L_c)$ and $\pi(LS_c)$ which using the LongTR and LSTR from π_c to identify critical decisions but executing the policy π to make decisions. In general, the original DQN should converge faster and generate better policy than the Critical DQN.

3. SIMULATION ENVIRONMENT

3.1 GridWorld Description

The GridWorld environment is like a maze that the agent learns an optimal path from the start point to the end point. Figure 2 shows our GridWorld environment, which consists of 7 by 14 cells. The agent starts from the start state (right bottom corner), explores the 2D space and finishes at the end state (left upper corner). There are several walls in the GridWorld which are marked as black blocks. The agent state is simply represented by the X and Y coordinates.

Figure 2: The Interface of the GridWorld Game

Action At each step, the agent can take three actions: up, down and left. In Figure 2, the possible actions for each state are labeled as small purple triangles that some states have three possible actions while some have two or one possible actions. The possible actions for each state are predefined in the environment so that the agent never hit the wall or the boundary.

Reward When moving in the GridWorld, there is -0.1 reward penalty for each step and the agent can collect -1 and +1 rewards. In order to simulate the real world, the reward function is designed in state-action-state way, $R(s, a, s')$. The black arrows indicate that only enter the reward state along with the arrow, the agent can get the reward -1 or +1. Otherwise, the agent won’t receive rewards. Furthermore, when the agent hits the reward state, it is forced to move left. This design aims to avoid the agent from collecting the same +1 reward repeatedly without forwarding to the terminal state.

Deterministic vs. Stochastic There are two transition settings in the GridWorld game: deterministic and stochastic. For deterministic transition setting, the next state is determined by the current state and action. For stochastic transition setting, the same state-action pair can result in different next states. For example, for deterministic setting, if the agent takes action ‘left’, then it will move to the left neighbor cell with 100 probability. For the stochastic transition setting, if the agent takes action ‘left’, then it only has 85% chance moving left, and 15% chance moving to other possible directions.

Finally, the performance of RL-induced policy in the GridWorld is evaluated by the final delayed reward which is the cumulative rewards during a trial. A good RL-induced policy should collect more +1 rewards, avoid -1 rewards and spend less steps to reach the goal.

3.2 Experiment Setup

Data Collection Since we focus on applying offline RL approaches to induce pedagogical policies, we induce all GridWorld policies offline. Following the data collection procedure in ITS, we collected the training data using a random policy. For the deterministic environment, we collected 500 randomly generated trajectories. Considering that the stochastic environment is more complicated, we collected

1000 trajectories for it.

Inferring Immediate Rewards Our LSTR framework requires immediate rewards to identify critical decisions, but our ITS data only have delayed rewards. Thus, we apply a Neural Network (NN) based approach to infer “immediate” rewards from delayed rewards. Given a trajectory to the NN as input, it outputs an “inferred” immediate reward for each step in the trajectory. The NN is trained using an additive error (the mean square error between the sum of inferred immediate rewards and the delayed rewards) as the loss function.

Critical Threshold Determination A key thing for identifying critical decisions is to choose an appropriate threshold on the long term and short term rewards that would not include too many trivial decisions but at the same would not exclude too many critical decisions. In order to pick a proper one, we conducted an analysis on the real and inferred immediate rewards and the Q-value difference. For immediate rewards, we would want to collect the large positive rewards and avoid the large negative rewards. Thus, rewards with a large absolute value should be considered as critical. Figure 3 shows the distribution of the real and inferred immediate rewards on the deterministic training dataset. The X axis shows the percentage of decisions in the dataset ranked by the value of the rewards (from large to small), and the Y axis shows value of the rewards. The threshold was set by allowing the real and critical rewards to identify similar numbers of critical decisions, which resulted in the value of 0.5. That is, if the ShortTR of a decision is greater than 0.5 or less than -0.5, it is critical. The same threshold was used for the stochastic dataset.

Figure 3: Immediate Reward Distribution

With the determined ShortTRs threshold, we explore different thresholds for the LongTRs in the experiment. The larger the threshold is (on percentage ranking), the more decisions will be carried out following the policy and the performance will in turn be better. To find a good balance between the number of critical decisions and the performance of the policy, we apply the policy with different thresholds (on percentage) at a 10% interval from 0% to 100% (0%, 10%, 20% ... 100%). Figure 4 shows an example distribution of the Q-value difference (LongTRs), calculated using the π policy in the deterministic dataset. For LSTRs, the critical decisions are the union from two set of critical decisions identified by LongTRs and ShortTRs separately.

Figure 4: Q-value Difference Distribution

3.3 Results

We evaluate the performance of the six critical policies across two types of environment (deterministic vs. stochastic) with two types of immediate rewards (real vs. inferred). Figure 5 to Figure 8 shows the online evaluation results for the four possible settings. The X axis shows the percentage of decisions identified as critical ones based on the LongTRs on the training data. For example, 10% means the decisions with the top 10 percent LongTRs were considered as critical. The Y axis shows the cumulative rewards (the average of 100 trials under different random seeds) received by each critical policy. As expected, across all four figures, there is a general trend that the more decisions considered as critical, the better the policy will perform.

Overall, $\pi_c(LSc)$ and $\pi(LSc)$ outperforms the other four policies across all four settings. This suggests that when identifying critical decisions, LSTRs are more effective than LongTRs and Critical DQN is more effective than original DQN. This supported our expectation that both long term and short term rewards should be considered in critical decision identification and Critical DQN provides a better estimation of the long term rewards when the policies are partially carried out.

Next, we investigate in detail how the execution policy and the rewards (long term vs. long-short term) may impact the performance of the critical policies. More specifically, we present our results in five parts. First, compare the effectiveness of the original and Critical DQN on LongTRs. Second, investigate whether LSTRs can lead to better performance than LongTRs. Third, a mixed comparison between the critical decision recognition and policy execution. Fourth, exam the effectiveness of the inferred rewards. Finally, explore the performance of the Critical DQN with limited amount of training data.

3.3.1 Original DQN vs. Critical DQN on LongTRs

We first focus on comparing the original DQN policy $\pi(L)$ and the Critical DQN policy $\pi_c(L_c)$ with LongTRs, where the same policy was used for both execution and critical decisions identification. As we can see in all four figures, $\pi_c(L_c)$ outperformed $\pi(L)$ when no more than 50% decisions were considered as critical. More importantly, the fewer the critical decisions, the larger the gap is (except 0% which is totally random). This suggests that the Q-value difference in π_c is

Figure 5: Deterministic GridWorld with Imm

Figure 6: Deterministic GridWorld with Infer

Figure 7: Stochastic GridWorld with Imm

Figure 8: Stochastic GridWorld with Infer

more accurate and sensitive than that in π in identifying critical decisions. This result is not surprising because the Critical DQN already took the random execution of non-critical decisions into account in policy induction. Additionally, as expected, as the percentage of critical decisions increasing, both policies reached optimal. This suggests that our proposed Critical DQN could generate optimal policies as the DQN can do.

3.3.2 LSTRs vs. LongTRs

Second, we investigate how different rewards (LSTRs vs. LongTRs) may impact the performance of the policies. LSTR policies are shown in solid lines while LongTR policies are shown in dashed lines across Figure 5 to Figure 8. Here we focus on comparing the pair of policies with the same execution and critical decision identification policies such as $\pi(L)$ vs. $\pi(LS)$ and $\pi(Lc)$ vs. $\pi(LSc)$. Overall, results showed that the LSTR policies outperformed the LongTR policies when no more than 50% decisions were considered as critical (with few exceptions where the two policies have equal performance). More importantly, the performance of the LSTR policies had a sharp increase in the interval of 0% to 50% while the increase of the LongTR policies was relatively smooth. This resulted in a large gap between them when few decisions were considered as critical. This gap

gradually diminished as more decisions were included and disappeared eventually. This suggests that considering both the long term and short term rewards is more effective than considering the long term rewards only, especially when few decisions were considered as critical.

3.3.3 Mixed Comparison

There are two factors in the critical policy: execution policy and Rewards for critical decision identification. In this comparison, we fixed one factor and examined the impact of the other one on the critical policy. First, through fixing the execution policy as π , a comparison between Lc vs. L showed that the $\pi(Lc)$ outperformed the $\pi(L)$ across all the four Figures 5 to 8. Similar to this setting, we can get the same results that $\pi(LSc)$ is better than $\pi(LS)$. It means that the LSTRs in Critical DQN policy is more accurate to identify critical decisions than the original DQN. When fixing the Rewards for critical decision identification as Lc , a comparison between π vs. π_c showed that $\pi(Lc)$ and $\pi_c(Lc)$ have similar performance. This result also applies to $\pi(LSc)$ and $\pi_c(LSc)$. It indicates that the policy π and π_c could make similar decisions on critical points and the Critical DQN could induce optimal policy as the original DQN.

3.3.4 Inferred Rewards vs. Immediate Rewards

We also examined the effectiveness of the inferred immediate rewards by comparing them with real rewards. Figure 5 and 7 show the policies (immediate critical policy) induced using real immediate rewards; while Figure 6 and 8 show the policies (inferred critical policy) induced using inferred rewards. Through comparing the performance at 100%, all the inferred critical policies could reach the same optimal with the immediate critical policies in both deterministic and stochastic environments. This suggests that the inferred rewards could generate the optimal policy as real rewards. Then, the lines of inferred critical policies in Figure 6 and 8 have similar trend patterns with the lines in Figure 5 and 7, respectively. It means that the LSTRs calculated by inferred critical policies have similar distribution with the ones from immediate critical policies. In sum, the result indicates that inferred rewards could not only generate the optimal policy but also produce reliable LSTRs.

3.3.5 Data-Efficiency for Critical DQN

From the previous results, we could get a conclusion that when the policies π and π_c are both optimal, $\pi_c(L_c)$ is better than $\pi(L)$ regarding the identification of critical decisions. But what if we don't have enough data to train an optimal policy, how's the critical DQN performing?

Figure 9: Original DQN vs. Critical DQN

Figure 9 shows the online performance of $\pi_c(L_c)$ vs. $\pi(L_c)$ and $\pi_c(LSc)$ vs. $\pi(LSc)$ as the number of training trajectories increasing. The X axis is the number of trajectories used to train the critical policies. The Y axis is the cumulative rewards (the average of 100 trails under different random seed) received by each critical policy. In this experiment, we applied the same rule to identify critical decision points for all the four policies and the only difference is which RL policy makes decision on the critical decision points. For $\pi(L_c)$, it means the critical decisions are identified by the LongTRs in π_c but execute π to make decisions in the online evaluation. It is the same for $\pi(LSc)$ that the LSTRs come from π_c while π decides what action to take. More specifically, the threshold for critical decisions is fixed by applying the same 0.5 threshold on short term rewards and 50% threshold on long term rewards.

The result shows that when the training dataset is less than 600 trajectories, the Critical DQN policies are worse than the original DQN policies. When the training dataset is

larger than 600 trajectories, they have similar performance. This suggests that the Critical DQN needs more data to converge to the optimal policy. But the LSTRs in Critical DQN is always good as the red lines $\pi(L_c)$ and $\pi(LSc)$ keep staying in the upper area from 100 to 1000 training trajectories. In summary, the Critical DQN could provide the best LSTRs to identify critical decisions but it needs more data to make good decision.

4. REAL-WORLD APPLICATION

4.1 Pyrenees Tutor Description

Pyrenees tutor is a web-based ITS for probability. It covers 10 major principles of probability, such as the Addition Theorem and Bayes' Rule. Pyrenees tutor provides step-by-step instruction and immediate feedback. Pyrenees tutor can also provide on-demand hints prompting the student with what they should do next. As with other systems, help in Pyrenees tutor is provided via a sequence of increasingly specific hints. The last hint in the sequence, the bottom-out hint, tells the student exactly what to do.

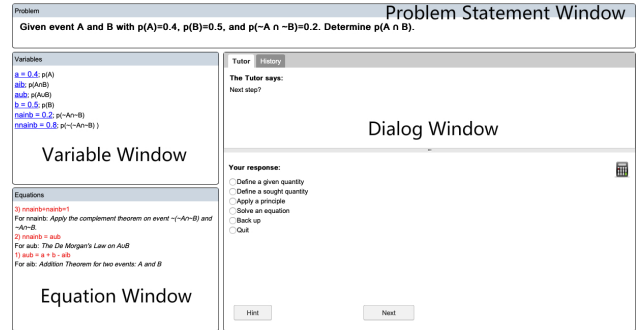

Figure 10: The Interface of the Pyrenees Tutor

Figure 10 shows the interface of Pyrenees, which consists of four windows. The top window shows the problem statement and doesn't change throughout the problem. In the dialog window, the upper part shows the instructions the tutor gives to the students such as an explanation of the current step or a prompt for the next step. At the same time, student enters an answer in the lower part of the dialog window such as selecting a choice or writing an equation. Any variables or equations generated through this process are shown on the left side of the screen for reference.

During tutoring, students are required to complete 4 phases: 1) pre-training, 2) pre-test, 3) training, and 4) post-test. In the pre-training phase, all students study the domain principles through a probability textbook by reviewing some examples and solving certain training problems. In the second phase, students take a pre-test which contains 14 problems. More specifically, the textbook is not available at this phase and students are not given feedback on their answers, nor are they allowed to go back to earlier questions. This is also true for the post-test. In phase 3, all students receive the same 12 rather complicated problems in the same order on Pyrenees tutor. Each of the 10 major principles needs to be applied at least twice in the training problems. For each problem, the average solving steps range from 20 to 50. Different from the pre- and post- test, students can access the

corresponding pre-training textbook and tutor help is available during this phase. Most importantly, the pedagogical policy works in this phase by deciding what action to take for each problem. In the training phase, each problem could have been provided as problem solving or worked example. Also, each step in the problem could have been provided as either a tell or elicit. Finally, all of the students complete a post-test with 20 problems. 14 of the problems are isomorphic to the pre-test given in phase 2. The remaining six are non-isomorphic complicated problems.

The performance of student learning is measured by the *normalized learning gain* (NLG) which is defined as $NLG = \frac{posttest - pretest}{1 - pretest}$ where 1 is the maximum score for both pre- and post- test. When grading the pre- and post- test, we use partial credit that each problem score is defined by the proportion of correct principle applications evident in the solution. For example, a student who correctly applied 4 of 5 possible principles would get a score of 0.8. All of the tests are graded in a double-blind manner by a single experienced grader. For comparison purposes, all test scores are normalized to the range of [0, 1].

4.2 Experiment Setup

Training Dataset Our training dataset contains a total of 1148 students' interaction log collected over six semesters' classroom studies (16 Fall to 19 Spring). The studies were assigned as a regular homework to students. During the studies, all students used the same tutor, followed the same general procedure, studied the same training materials, and worked through the same training problems.

From the student-system interaction logs, 142 features were extracted which describes the student learning state. All the 142 features can be categorized into five groups that **Autonomy** features describe the amount of work done by the student; **Temporal** features are the time related information during tutoring; **Problem Solving** features indicate the context of the problem itself; **Performance** features denote student's performance; and **Student Action** features record the student behavior information. For each problem, there are three possible actions: worked example (WE), problem solving (PS) and step decisions (SD). In WE, the student observes how the tutor solves a problem; in PS, the student solves the problem; in SD, student solves a portion of steps in a problem while the tutor shows how to solve the others. For reward, there's no immediate reward during tutoring and the delayed reward is the student's NLG.

Offline Learning and Evaluation The offline learning process follows the same process with the GridWorld in section 3.2. First, NN was applied to infer the immediate rewards for the training dataset. Then, critical policy π and π_c were induced based on the original DQN and the Critical DQN. Finally, we fixed the threshold of ShortTRs based on the elbows in the distribution and explored the relationship between different thresholds of LongTRs and the performance of the critical policies.

Different from the online evaluation in GridWorld game, we applied *off-policy* policy evaluation (OPE) metrics to evaluate the performance of the critical policies. In general, there are two types of OPE: model based and Importance Sam-

pling (IS) based. Song's work [12] showed that Per Decision Importance Sampling (PDIS) is the best metrics to evaluate the performance of RL-induced policies in the context of ITSs. So, PDIS was applied to evaluate the critical policies on the training dataset. More specifically, if a decision is identified as critical, the probability of taking that action is calculated by the softmax of Q-values among all the possible actions. On the contrary, if the decision is identified as non-critical, then the probability of taking that action is the random probability 1/3 as there are three possible actions for each problem.

4.3 Results

For Pyrenees tutor, we first present the offline evaluation results for all six critical policies. Then, we explore the identified critical decisions in the historical dataset.

4.3.1 Offline Evaluation Results

Figure 11 shows the offline evaluation results on Pyrenees tutor dataset. The X axis is the percentage of decisions identified as critical decisions in the historical dataset. The Y axis is the PDIS value. In general, the higher the PDIS, the better the policy.

Figure 11: Offline Evaluation Results

First of all, the trend still holds that the more critical decisions, the better the policy would perform. When comparing within the dashed lines, there's no clear pattern before 40% threshold. However, $\pi(L_c)$ significantly outperformed the other two critical policies after 40%. The same trend occurs on the solid lines with LSTRs. The reason is that the Pyrenees dataset is not large enough for the Critical DQN to find an optimal policy, but the L_c and LS_c are still accurate to identify critical decisions. Furthermore, the performance jump around 50% demonstrates the reliability of the Critical DQN algorithm because in the pseudo-code 1, we already decide half of the decisions are critical decisions and the Figure 11 reflects this setting. As expected, the LSTR still outperforms LongTR that all the solid lines are above the corresponding dashed lines. In summary, the result reflects the effectiveness of LSTR in identifying critical decisions.

4.3.2 Exploring Critical Decisions

Table 2: Distribution of Critical Decisions in each Problem

	P1	P2	P3	P4	P5	P6	P7	P8	P9	P10
Long-Term Rewards	3%	16%	16%	13%	15%	11%	7%	7%	6%	6%
Short-Term Rewards	0%	1%	6%	6%	6%	10%	13%	19%	19%	20%
Long-Short Term Rewards	3%	14%	15%	12%	14%	11%	8%	8%	8%	8%

In order to further investigate the critical decisions identified by LSTRs in the tutor dataset, we analyzed where did they occur. 50% threshold for the LS_c in Figure 11 was applied to identify critical decisions in the tutor dataset and Table 2 shows the distribution of critical decisions in each problem. The first row represents the 10 problems in chronological order. The second row indicates the percentage of critical decisions identified by LongTRs in different problems. For example, 3% of critical decisions happens in P1 while 16% happens in P2. It indicates that the LongTRs focus on the critical decisions in the early to mid stage. In the meantime, the third row shows that the ShortTRs focus on the critical decisions in the late stage. The fourth row shows the critical decisions identified by LSTRs, which is the union set of the critical decisions from LongTRs and ShortTRs. Overall, critical decisions are evenly distributed among all the problems except the first one. It is not surprising that the first one is not so important because in the first problem, students are not familiar with the system and the policy needs more data to know the student status better. Furthermore, it reflects that the LongTRs and ShortTRs complement each other. If we only focus on LongTRs, we will miss the important decisions in the late stage, otherwise we will miss the important decisions in the early to mid stage.

5. RELATED WORK

5.1 RL For Pedagogical Policy Induction

Prior Research in Applying RL to Pedagogical Policy Induction can be roughly divided into classic RL vs. Deep RL approaches. The latter is highly motivated by the fact that the combination of deep learning (neural networks) and novel reinforcement learning algorithms has made solving complex problems possible in the last decade. For instance, the Deep Q-Network (DQN) algorithm [18] takes advantage of convolutional neural networks to learn to play Atari games observing the pixels directly. Since then, DRL has achieved success in various complex tasks such as the games of Go [25], Chess/Shogi [26], and robotic control [3]. One major challenge of these methods is *sample inefficiency* where RL policies need large sample sizes to learn optimal, generalizable policies. Batch RL, a sub-field of RL, aims to fix this problem by learning the optimal policy from a fixed set of a priori-known transition samples [15], thus efficiently learning from a potentially small amount of data and being able to generalize to unseen scenarios.

Prior research using classic RL approaches has applied both online and batch/offline approaches to induce pedagogical policies for ITSs. Beck et al. [4] applied temporal difference learning to induce pedagogical policies that would minimize the students’ time on task. Similarly, Iglesias et al. applied Q-learning to induce policies for efficient learning [10]. More recently, Rafferty et al. applied an online partially observable Markov decision process (POMDP) to induce policies for faster learning [19]. All of the models described above

were evaluated via simulations or classroom studies, yielding improved student learning and/or behaviors as compared to some baseline policies. Offline or batch RL approaches, on the other hand, “take advantage of previous collected samples, and generally provide robust convergence guarantees” [22]. Thus, the success of these approaches depends heavily on the quality of the training data. One common convention for collecting an exploratory corpus is to train students on ITSs using *random yet reasonable* policies. Shen et al. applied value iteration and least square policy iteration on a pre-collected exploratory corpus to induce a pedagogical policy that improved students’ learning performance [24, 23]. Chi et al. applied policy iteration to induce a pedagogical policy aimed at improving students’ learning gain [5]. Mandel et al. [16] applied an offline POMDP to induce a policy which aims to improve student performance in an educational game. All the models described above were evaluated in classroom studies and were found to yield certain improved student learning or performance relative to a baseline policy. Wang et al. applied an online DRL approach to induce a policy for adaptive narrative generation in educational game using simulations [29]; the resulting DRL-induced policies were evaluated via simulations only. In this work, based on the characteristics of our task domain, we focus on batch RL with neural networks, also known as batch Deep Reinforcement Learning (batch DRL) [11, 9].

5.2 Critical Decisions in Simulation

Student-Teacher framework is the most closely related work to our problem. In this framework, a “student” agent learns from the interaction with environment, while a “teacher” agent provides action suggestions to accelerate the learning process. Their research question is not what to advise but when to advise, especially with a limited budget of advice.

Clouse [7] was the first one studied the student-teacher framework in a student-initiated advising mode. They applied Q-value difference to measure the student’s confidence in a state and used it to decide when should the student ask for help. The results showed that compared with random asking, their approach could improve the learning speed significantly. Furthermore, the experiment demonstrated that not all the teacher’s advice are equally helpful. The same amount of advice can cause the student agent to take widely varying amounts of steps to find the optimal policy.

Torrey et al. [28] considered the student-teacher framework in teacher-initiated advising way. They considered an environment with a limited budget of advice and teacher decided when to give advice. They proposed several heuristic methods to determine when to give advice such as early advising, importance advising, mistake correcting and predictive advising. The results showed that mistake correcting has the best performance which indicates that advice can have the greatest impact when students make mistakes on important

states.

Zimmer et al. [33] modeled the when to advise problem as an RL problem. They learned a teaching policy with two actions: $A = \text{advise}, \text{noadvise}$ to decide when to give advice to the student. Compared with heuristic methods, the result showed that the teacher policy is effective because it can learn not only when to give advice, but also distinguish good and bad student agent that good agent chooses a lot of good actions and doesn't need advice while bad agent needs more.

Amir et al. [1] studied the jointly-initiated strategies for student-teacher learning framework. In their model, both student and teacher can initiate advising based on heuristic functions. The motivation of their work is to reduce the pressure of the teacher agent on monitoring the student constantly and make the framework more close to the real-life student-agent scenario. The result showed that the joint decision-making approach could reduce the attentions required from the teacher but still keep the student learning effectively.

Fachantidis et al. [8] explored the impact of advice quality in the student-teacher framework. They distinguished teacher agents to be an expert or a good teacher who provide optimal or sub-optimal advice. Also, a Q-teaching method was proposed to learn a teaching policy to decide when to give advice. Their results showed that the best performers are not always the best teachers and the Q-teaching approach is significantly more efficient than others.

In summary, prior works investigated the problem of when to give advice in simulated environments. They showed that Q-value difference is a robust and accurate heuristic function to estimate the importance of decision in interactive environments. However, prior works only considered RL-based student agent but not human students. In this work, we expand to a dataset of real-world ITS involving human students.

5.3 Exploiting Q-value Difference in ITSs

Some prior work exploited the Q-value difference between actions to simplify the decision-making process/problem in the context of ITS. For example Mitchell et al. relied on the Q-value difference to reduce the feature space [17]. More specifically, they proposed a policy evaluation metric, separation ratio for feature selection, which is defined as $\frac{2 * |Q(s, a_1) - Q(s, a_2)|}{(Q(s, a_1) + Q(s, a_2))}$ where $Q(s, a_i)$ is the Q value for the state-action pair (s, a_i) . The feature selection approach was then combined with RL to induce pedagogical policies for a dialog system, the Java tutor.

Zhou et al. [31] relied on Q-value difference to reduce the policy space. More specifically, they applied weighted decision tree with post-pruning to extract a compact set of 529 rules from a full set of 3706 rules. During the extraction, each rule was weighted by the Q-value difference between two alternative actions and thus increased the carry-out likelihood of more important decisions. The policies were empirically evaluated in a classroom study. Results showed that the full RL policy and the compact DT policy together were significantly more effective than a random policy and there is no significant difference between the full RL policy and

the compact DT policy.

Song et al. [13] proposed an ADRL framework to identify critical decisions and conducted an empirical study to test the effectiveness of the ADRL. In ADRL, two policies were induced that a positive policy aims to help student while a bad policy tries to hinder student learning. For a given state, if the two policies have different decisions and the Q-value difference is large enough, then this is a critical state and the decision is important. The results showed that critical phase exists in student learning that critical decisions always occur in groups and the more critical phase students have experienced, the better performance they have.

In sum, prior studies have considered the Q-value difference between actions as a heuristic function of action importance. The larger the difference, the more important the decision is. However, prior work didn't quantitatively study how large Q-value difference is a critical decision. In this work, we explored the Q-value difference thresholds by classifying decisions into two categories: critical and non-critical and evaluating the quality of the critical decisions.

6. CONCLUSIONS

In this study, we explored Long-Short Term Rewards to identify critical decisions in both synthetic Gridworld game and real-world ITS. Based on the LSTRs, we proposed Critical DQN to induce critical policy whose Q-value difference is more heuristic and sensitive to the decision importance. In order to investigate the effectiveness of LSTRs, we evaluated the performance of critical policies with different critical thresholds by online evaluation on GridWorld and offline evaluation on Pyrenees tutor's dataset. The results showed that the LongTRs from Critical DQN are significantly better than the original DQN. Through considering the ShortTRs, the LSTRs are significantly better than the LongTRs. However, the Critical DQN needs more data to converge to an optimal policy. In summary, through identifying critical decisions by the LSTRs, half of the decisions are trivial and carry out the optimal policy on the 50% decisions (critical ones) could achieve the similar effect of carrying out on all decisions.

In the future, we plan to generalize the LSTR framework to other domains in terms of interactive environments. Also, we hope to deploy a critical DQN policy on Pyrenees tutor and only carry out 50% decisions in a classroom study to test the critical decisions empirically.

ABSTRACT

With the rapid emergence of K-12 online learning platforms, a new era of education has been opened up. It is crucial to have a dropout warning framework to preemptively identify K-12 students who are at risk of dropping out of the online courses. Prior researchers have focused on predicting dropout in Massive Open Online Courses (MOOCs), which often deliver higher education, i.e., graduate level courses at top institutions. However, few studies have focused on developing a machine learning approach for students in K-12 online courses. In this paper, we develop a machine learning framework to conduct accurate at-risk student identification specialized in K-12 multimodal online environments. Our approach considers both online and offline factors around K-12 students and aims at solving the challenges of (1) multiple modalities, i.e., K-12 online environments involve interactions from different modalities such as video, voice, etc; (2) length variability, i.e., students with different lengths of learning history; (3) time sensitivity, i.e., the dropout likelihood is changing with time; and (4) data imbalance, i.e., only less than 20% of K-12 students will choose to drop out the class. We conduct a wide range of offline and online experiments to demonstrate the effectiveness of our approach. In our offline experiments, we show that our method improves the dropout prediction performance when compared to state-of-the-art baselines on a real-world educational dataset. In our online experiments, we test our approach on a third-party K-12 online tutoring platform for two months and the results show that more than 70% of dropout students are detected by the system.

Dropout, retention, multimodal learning, online tutoring, K-12 education

1. INTRODUCTION

^{*}The corresponding author.

Hang Li, Wenbiao Ding, Songfan Yang and Zitao Liu "Identifying At-Risk K-12 Students in Multimodal Online Environments: A Machine Learning Approach" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 137 - 147

With the recent development of technologies such as digital video processing and live streaming, there has been a steady increase in the amount of K-12 students studying online courses worldwide. Online classes have become necessary complements to public school education in both developing and developed countries [31, 27, 37, 42, 35, 34, 36]. Different from public schools that focusing on teaching in traditional brick-and-mortar classrooms with 20 to 50 students, online classes open up a new era of education by incorporating more personalized and interactive experience [20, 33, 45, 9, 57].

In spite of the advantages of this new learning opportunity, a large group of online K-12 students fail to finish course programs with little supervision either from their parents or teachers. Students drop out of the class may be due to many reasons such as lack of interests or confidence, mismatches between course contents and students' leaning paths or even no immediate grade improvements from their parents' perspectives [37, 39, 25]. Therefore, it is crucial to build an early dropout warning system to identify such at-risk online K-12 students and provide timely interventions.

A large spectrum of approaches have been developed and successfully applied in predicting dropout in Massive Open Online Courses (MOOCs) [29, 47, 43, 58, 3, 5]. However, identifying dropout of K-12 students on online courses are significantly different from MOOCs based attrition prediction. The main differences are summarized as follows:

- **watching v.s. interaction:** Even though both learning are conducted in the online environment, learners' engagements on MOOCs and K-12 online platforms vary a lot [20]. In MOOCs, learners mainly watch the pre-recorded video clips and discuss questions and assignments with teaching assistants on the MOOC forums [18]. While in K-12 online courses, students frequently interact with the online tutors in a multimodal and immersive learning environment. The tutors may answer students' questions, summarize the knowledge points, take notes for students, etc.

- **spontaneous action v.s. paid service:** Learners on existing popular MOOC platforms such as Coursera¹, edX², etc. are adults, who aim at continuing

¹<https://www.coursera.org/>

²<https://www.edx.org/>

their lifelong learning in higher education and obtaining professional certificates such as Coursera’s Specializations and edX’s MicroMasters. MOOC learners are typically self-motivated and self-driven. On the contrary, most available K-12 online education choices are commercialized in service industry. Students pay to enroll online tutoring programs to strengthen their in-class knowledge levels and improve their grades in final exams. As a result, there are numerous out-of-class activities involved in K-12 online learning such as follow-ups from personal instructors, satisfaction survey and communications with students’ parents, etc. These out-of-class activities rarely appear in MOOC based learning.

- **high v.s. low dropout rate:** The dropout rate for MOOC based program is often as high as 70% - 93% [31, 52] while the dropout rate in K-12 online courses is below 20%.

Therefore, it is important to study approaches to identify at-risk K-12 online students and build an effective yet practical warning system. However, this task is rather challenging due to the following real-world characteristics:

- **multiple modalities:** K-12 online learning is conducted in an immersive and multimodal environment. Students and instructors interact with each other visually and vocally. There are a lot of multimodal factors that may influence the final decisions of dropout, ranging from interaction qualities between students and teachers, teaching speeds, volumes, emotions of the online tutors, etc.
- **length variability:** Students join and leave the online platforms independently, which results in a collection of observation sequences with different lengths. A dropout prediction system should be able to (1) make predictions for students with various lengths of learning histories; and (2) handle newly enrolled students.
- **data imbalance:** The overall dropout rate for K-12 online classes is usually below 20%, which makes the training samples particularly imbalanced.

The objective of this work is to study and develop models that can be used for accurately identifying at-risk K-12 students in multimodal online environments. More specifically, we are interested in developing models and methods that can predict risk scores (dropout probabilities) given the history of past observations of students. We develop a data augmentation technique to alleviate class imbalance issues when considering the multi-step ahead prediction tasks. We conduct extensive sets of experiments to examine every component of our approach to fully evaluate the dropout prediction performance.

Overall this paper makes the following contributions:

- We design various types of features to fully capture both in-class multimodal interactions and out-of-class

activities. We create a data augmentation strategy to simulate the time-sensitive changes of dropout likelihood in real scenarios and alleviate the data imbalance problem.

- We design a set of comprehensive experiments to understand prediction accuracy and performance impact of different components and settings from both qualitative and quantitative perspectives by using a real-world educational dataset.
- We push our approach into a real production environment to demonstrate the effectiveness of our proposed dropout early warning system.

The remainder of the paper is organized as follows: Section 2 discusses the related research work of dropout prediction in both public school settings and MOOCs scenarios. Comparisons with relevant researches are discussed. In Section 3, we introduce assumptions when building a practical at-risk student identification system and formulate the prediction task. Section 4, we describe the details about our prediction framework, which include (1) extracting various types of features from both online classroom recordings and offline activity logs (See Section 4.1); and (2) data augmentation technique that helps us create sufficient training pairs and overcomes the class imbalance problem (See Section 4.2). In Section 5, we (1) quantitatively show that our model supports better dropout predictions than alternative approaches on an educational data derived from a third party K-12 online learning platform and (2) demonstrate the effectiveness of our proposed approach in the a real production environment. We summarize our work and outline potential future extensions in Section 6.

2. RELATED WORK

Dropout prediction and at-risk student identification have been gaining popularity in both the educational research and the AI communities. Understanding the reasons behind dropouts and building early warning systems have attracted a growing interest of academics in the learning analytics area. Broadly speaking, existing research regarding dropout prediction can be categorized by learning scenarios and divided into two categories: (1) public school dropout (See Section 2.1); and (2) MOOCs dropout (See Section 2.2).

2.1 Public School Dropout

Education institutions are faced with the challenges of low student retention rates and high number of dropouts [45, 32]. For examples, in the United States, almost one-third of public high school students fail to graduate from high school each year [40, 7] and over 41% of undergraduate students at four-year institutions failed to graduate within six years in Fall 2009 [38]. Hence, research work has focused on predicting the dropout problem and developing dropout prevention strategies [40, 41, 8, 55, 13, 30, 10, 49]. Zhang and Rangwala develop an at-risk student identification approach based on iterative logistic regression that utilizes all the information from historical data from previous cohorts [59]. The state of Wisconsin creates a predictive dropout early warning system for students in grades six through nine and provides predictions on the likelihood of graduation for over

225,000 students [30]. The system utilizes ensemble learning and is built on the steps of searching through candidate models, selecting some subsets of best models, and averaging those models into a single predictive model. Lee and Chung address the class imbalance issue using the synthetic minority over-sampling techniques on 165,715 high school students from the National Education Information System in South Korea [33]. Ameri et al. consider different groups of variables such as family background, financial, college enrollment and semester-wise credits and develop a survival analysis framework for early prediction of student dropout using Cox proportional hazards model [1].

2.2 MOOCs Dropout

With the recent boom in educational technologies and resources both in industry and academia, MOOCs have rapidly moved into a place of prominence in the mind of the public and have attracted a lot of research attentions from many communities in different domains. Among all the MOOC related research questions, dropout prediction problem emerges due to the surprisingly high attrition rate [54, 19, 26, 23, 44, 56, 6, 11, 12, 20]. Ramesh et al. treat students' engagement types as latent variables and use probabilistic soft logic to model the complex interactions of students' behavioral, linguistic and social cues [43]. Sharkey et al. conduct a series of experiments to analyze the effects of different types of features and choices of prediction models [47]. Kim et al. study the in-video dropouts and interaction peaks, which can be explained by five identified student activity patterns [25]. He et al. propose two transfer learning based logistic regression algorithms to balance the prediction accuracy and inter-week smoothness [21]. Tang et al. formulate the dropout prediction as a time series forecasting problem and use a recurrent neural network with long short-term memory cells to model the sequential information among features [50]. Both Yang et al. and Mendez et al. conduct survival analysis to investigate the social and behavioral factors that affect dropout along the way during participating in MOOCs [58, 39]. Detailed literature surveys on MOOC based dropout prediction are reviewed comprehensively in [51, 5].

In this work, we focus on identifying at-risk students in K-12 online classes, which is significantly distinguished from dropout predictions in either public school or MOOCs based scenarios. In the K-12 multimodal learning environment, the learning paradigm focuses on interactions instead of watching. The interactions come from different modalities, which rarely happen in traditional public schools and MOOC based programs of higher education. Furthermore, as a paid service, K-12 online learning involves both in-class and out-of-class activities and both of them contain multiple factors that could lead to class dropouts. These differences make existing research works inapplicable in K-12 online learning scenarios. To the best of our knowledge, this is the first research that comprehensively studies the dropout prediction problem in K-12 online learning environments from real-world perspectives.

3. PROBLEM FORMULATION

3.1 Assumptions

In order to characterize the K-12 online learning scenarios, we need to carefully consider every cases in the real-world

environment and make reasonable assumptions. Without loss of generality, we have the following assumptions in the rest of the paper.

ASSUMPTION 1 (RECENCY EFFECT). *Time spans between the date of dropout and the date of last online courses vary a lot. Students may choose to drop the class right after one course or quit after two weeks of no course. Therefore, the per-day likelihood of dropout should be time-aware and the closer to the dropout date, the more accurate the dropout prediction should be.*

ASSUMPTION 2 (MULTI-STEP AHEAD FORECAST). *The real-world dropout prediction framework should be able to flexibly support multi-step ahead predictions, i.e., the next-day and next-week probabilities of dropout.*

3.2 The Prediction Problem

In this work, our objective is to predict the value of future status for the *target student* given his or her past learning history, i.e., observations collected from K-12 online platforms. More specifically, let \mathbf{S} be the collection of all students and for each student $s, s \in \mathbf{S}$, we assume that we have observed a sequence of n_s past observation-time pairs $\{< \mathbf{x}_j^s, t_j^s > \}_{j=1}^{n_s}$, $\mathbf{x}_j^s \in \mathbf{X}^s$, and $t_j^s \in \mathbf{T}^s$, such that $0 < t_j^s < t_{j+1}^s$, and \mathbf{x}_j^s is the observation vector made at time (t_j^s) for student s . \mathbf{X}^s and \mathbf{T}^s represent the collections of observations and timestamps for student s . Correspondingly, let \mathbf{Y}^s be the collection of indicators of status (*dropout, ongoing or completion*) of student s at each timestamp, i.e., $\mathbf{Y}^s = \{y_j^s\}_{j=1}^{n_s}$. Let Δ be the future time span in multi-step ahead prediction. Time $t_{n_s+\Delta}^s$ ($\Delta > 0$) is the time at which we would like to predict the student's future status $\hat{y}_{t_{n_s+\Delta}^s}^s$.

Please note that we omit the explicit student index s in the following sections for notational brevity and our approach can be generalized into a large samples of student data without modifications.

4. THE PREDICTION FRAMEWORK

The dropout prediction for K-12 online courses is a time-variant task. A student who just had the class should have a smaller dropout probability compared with a student haven't take any class for two weeks. Therefore, when designing a real applicable approach of dropout prediction, such recency effect, i.e., Assumption 1, has to be considered. In this work, we extract both static and time-variant features from different categories to capture the factors leading to dropout events comprehensively (See Section 4.1). Furthermore, we create a label augmentation technique that not only alleviates the class imbalance problem when building predictive framework for K-12 online classes, but incorporates the recency effect into label constructions (See Section 4.2). The learning of our dropout model is discussed in Section 4.3 and the overall learning procedure is summarized in Section 4.4.

4.1 Features

In this section, we develop a distinguished set of features for at-risk student identification from the real-world K-12 online learning scenarios, which can be divided into three categories: (1) in-class features that focus on K-12 students'

online behaviors during the class (See Section 4.1.1); (2) out-of-class features that consider as much as possible real-world factors happened after the class, which may influence the dropout decisions (See Section 4.1.2); and (3) time-variant features that include both historical performance of teachers and aggregated features of student activities within fixed-size windows (See Section 4.1.3).

4.1.1 In-class Features

Different from adults who continue their learning in higher education on MOOC based platforms, K-12 students come for grade improvements. This intrinsic difference in their learning goals leads to contrasting learning behaviors. Adult learners of MOOCs study independently by various activities, such as viewing lecture videos, posting questions on MOOC forums, etc. This results in various types of in-class click-stream data, which are shown to be effective in dropout prediction in many existing research works [15, 51, 54, 6, 12, 11, 20]. However, such click based activities barely happen in K-12 online scenarios. Instead, there are frequent voice based interactions between K-12 students and their teachers. The teachers not only make every effort to clarify unsolved questions that students remain from their public schools, but are responsible for arousing students' learning interests and building their studying habits. Therefore, we focus on extracting in-class multimodal features specializing in K-12 tutoring scenarios from the online classroom videos. We categorize our features as follows. Table 1 illustrates some examples of in-class features from different categories.

- **Prosodic features:** speech-related features such as signal energy, loudness, Mel-frequency cepstral coefficients (MFCC), etc.
- **Linguistic features:** language-related features such as statistics of part-of-speech tags, the number of interregnum words, distribution of length of sentences, voice speed of each sentence, etc.
- **Interaction features:** features such as the number of teacher-student Q&A rounds, the numbers of times teachers remind students to take notes etc.

To extract all the features listed in Table 1, we first extract audio tracks from classroom recordings on both teacher's and student's sides. Then we extract acoustic features directly from classroom audio tracks by utilizing the widely used open-sourced tool, i.e., *OpenSmile*³. We obtain classroom transcriptions by passing audio files to a self-trained automatic speech recognition (ASR) module. After that, we extract both linguistic and interaction features from the conversational transcripts. Finally, we concatenate all features from above categories and apply a linear PCA to get the final dense in-class features. The entire in-class feature extraction workflow of our approach is illustrated in Figure 1.

Please note that due to the benefits of online steaming, both students' and teachers' videos are recorded separately and hence, there is no voice overlap in the video recordings. This

³<https://www.audeering.com/opensmile/>

Figure 1: The workflow of our in-class features extraction. ASR is short for automatic speech recognition.

avoids the unsolved challenge of speaker diarization [2]. Similar to Blanchard et al. [4], we find that publicly available ASR service may yield inferior performance in the noisy and dynamic classroom environments. Therefore, we train our own ASR models on the classroom specific dataset based on a deep feed-forward sequential memory network, proposed by Zhang et al. [60]. Our ASR has a word error rate of 28.08% in our classroom settings.

4.1.2 Out-of-class Features

As we discussed in Section 1, personalized K-12 online tutoring is a paid service in most countries. Besides the course quality itself, there are multiple other factors in such service industry that may change customers' minds to drop the class. Therefore, out-of-class features play an extremely important role in identifying at-risk students in real-world K-12 online scenarios, which are typically ignored in previous literatures. In this work, we collect and summarize all the available out-of-class features and divide them into the following two categories. The illustrative examples are listed in Table 1.

- **Pre-class features:** Pre-class features capture the students' (or even their parents') behaviors before taking the class, such as purchasing behaviors, promotion negotiations, etc. Examples: the number of rounds of conversation and negotiation before the class, how much the discount student received, etc.
- **Post-class features:** Post-class features model the offline activities in such paid K-12 online services. For examples, students and their parents receive follow-ups based on their previous class performance and give their satisfaction feedbacks. Another example is that students may request changes to their course schedules.

4.1.3 Time-variant Features

Besides in-class and out-of-class features, we manually design time-variant features to model the changes of likelihood of students' dropout intentions. Cases like a student just had a class compared to a student had a class two weeks ago should be explicitly distinguished when constructing features. Therefore, we create time-variant features by utilizing a lookback window approach on students' observation sequences. More specifically, for a given timestamp, we only focus on previously observed activities of each student within a period of time. The length of lookback windows varies from 1 to 30 days. Sufficient statistics are extracted as time-variant features from each lookback window. Meanwhile, we

Table 1: List of examples in in-class, out-of-class, and time-variant features.

Category	Type	Examples
In-class	Prosodic	the average signal energies of student and teacher the average loudness of student and teacher the Mel-frequency cepstral coefficients of audio tracks from student and teacher the zero-crossing rates of student and teacher ...
	Linguistic	# of sentences per class of student and teacher # of pause words per class of student and teacher average lengths of sentences per class of student and teacher voice speeds (char per second) of student and teacher ...
	Interaction	# of teacher-student Q&A rounds # of times the teacher reminds the student to take notes and summarization # of times the teacher asks the student to repeat # of times the teacher clarifies the student's questions ...
Out-of-class	Pre-class	# of days since the student places the online course order # of courses in the student's order # of conversations between the sales staff and the students (or their parents) the discount ratio of the student's order ...
	Post-class	# of follow-ups after the student took the first class # of words in the latest follow-up report # of times the student reschedules the class the follow-up ratio, i.e., # of follow-ups divided by # of taken courses ...
Time-variant	Historical performance	# of courses taught by each individual teacher in total # of courses the student had in total historical dropout rates historical average time span between classes ...
	Lookback window	# of courses taken in past one/two/three weeks # of courses the student scheduled in past one/two/three weeks # of positive/negative follow-up reports in past one/two/three weeks the average time span of classes taken in past month ...

compute historical performance features to reflect the teaching experience and performance for each individual teacher. Table 1 shows some examples of time-variant feature we use in our dropout prediction framework.

- **Lookback window features:** The lookback window features aggregate important statistics from students' observations within a fixed-length lookback window, such as the numbers of courses taken in past one, two, three weeks.
- **Historical performance features:** The historical features aggregate each teacher's past teaching performance, which represent the overall teaching quality profiles. They include total numbers of courses and students taught, historical dropout rates, etc.

4.2 Data Augmentation

According to Assumptions 1 and 2 and the problem formulation in Section 3.2, a real-world early warning system is

supposed to flexibly support multi-step ahead predictions for each student, i.e., given any future time span Δ , the system computes the probability of student's status $\hat{y}_{t_{n_s}+\Delta}^s$. The predicted probability should be able to dynamically adapt when the values of Δ get changed. The multi-step ahead assumption essentially requires the approach to make predictions at a more fine-grained granularity of $\langle \text{student}, \text{timestamp} \rangle$ pair, i.e., $\langle s, t_{n_s+\Delta}^s \rangle$, instead of student level, i.e., s . This poses a challenging question: due to the fact that only about 20% of K-12 students drop their online classes, *how do we tackle the class imbalance problem when extracting $\langle \text{student}, \text{timestamp} \rangle$ training pairs from a collection of multimodal observation sequences (either completion or dropout) in K-12 online scenarios?*

Let \mathbf{S}_1 and \mathbf{S}_2 be the set of student indices of dropout and non-dropout students, i.e., $\mathbf{S}_1 = \{i | y_{n_i}^i = \text{dropout}\}$, and $\mathbf{S}_2 = \{j | y_{n_j}^j = \text{completion}\}$. Let \mathbf{P} and \mathbf{N} be the sets of positive (dropout) and negative (non-dropout) $\langle \text{student}, \text{timestamp} \rangle$ pairs. By definition, \mathbf{P} and \mathbf{N} are constructed as follows:

$$\begin{aligned}
\mathbf{P} &= \{ \langle \mathbf{x}_{n_i}^i, t_{n_i}^i \rangle \mid i \in \mathbf{S}_1 \} \\
\mathbf{N} &= \{ \langle \mathbf{x}_k^i, t_k^i \rangle \mid i \in \mathbf{S}_1, k \in \mathbf{T}_i \setminus t_{n_i}^i \} \\
&\cup \{ \langle \mathbf{x}_k^j, t_k^j \rangle \mid j \in \mathbf{S}_2, k \in \mathbf{T}_j \}
\end{aligned} \quad (1)$$

Similar to many researches such as fraud detection [53], the sizes of \mathbf{P} and \mathbf{N} are typically very imbalanced. While in some cases the class imbalance problem may be alleviated by applying an over-sampling algorithm on the minority class sample set, the diversity of the available instances is often limited. Therefore, in this work, we propose a time-aware data augmentation technique that artificially generates pseudo positive (dropout) $\langle \text{student}, \text{timestamp} \rangle$ pairs.

More specifically, for each dropout student i in \mathbf{S}_1 , we set a lookback window with length Λ where $\Lambda \leq t_{n_i}^i - t_{n_i-1}^i$. For each timestamp \tilde{t}_l^i in the lookback window such that

$$\max(t_{n_i-1}^i, t_{n_i}^i - \Lambda) < \tilde{t}_l^i < t_{n_i}^i. \quad (2)$$

We generate its corresponding pseudo positive training pair $\langle \tilde{\mathbf{x}}_l^i, \tilde{t}_l^i \rangle$ as follows: $\tilde{\mathbf{x}}_l^i = \mathcal{F}(\mathbf{X}^s, \mathbf{T}^s)$ where $\mathcal{F}(\cdot, \cdot)$ is the generation function. The choices of $\mathcal{F}(\cdot, \cdot)$ are flexible and vary among different types of features (See Section 4.1). In this work, for in-class and out-of-class features, we aggregate all the available features till \tilde{t}_l^i and re-compute the time-variant features according to timestamp \tilde{t}_l^i . We use $\tilde{\mathbf{P}}$ to represent the collection of all positive training pairs generated from dropout students in \mathbf{S}_1 . Figure 2 illustrates how the pseudo positive training pairs are generated.

Figure 2: Graphical illustration of the data augmentation technique.

Besides, we assign a time-aware weight to each pseudo positive training pair to reflect the recency effect in Assumption 1. For each pseudo pair $\langle \tilde{\mathbf{x}}_l^i, \tilde{t}_l^i \rangle$, the corresponding weight w_l^i is computed by

$$w_l^i = \mathcal{G}\left(\frac{t_{n_i}^i - \tilde{t}_l^i}{\Lambda}\right) \quad (3)$$

where the weighting function $\mathcal{G}(\cdot)$ takes the normalized time span between each timestamp of pseudo pair and the exact dropout date as input and outputs a normalized weighting score to reflect our confidence on the “positiveness” of the simulated training pairs. The closer to the dropout date, the

larger the confidence weights should be. The choices of $\mathcal{G}(\cdot)$ are open to any function that gives response values ranging from 0 to 1, such as linear, convex or concave functions illustrated in Figure 3.

Figure 3: Graphical illustration of different weighting function of $\mathcal{G}(\cdot)$.

The effect of different choices of weighting function is discussed in Section 5.4. The augmented training set $\tilde{\mathbf{P}}$ and the corresponding time-aware weights are used in the model training in Section 4.3.

4.3 Model Learning

In the learning stage, we combine the original training set (\mathbf{P} and \mathbf{N}) with the augmented set $\tilde{\mathbf{P}}$ for model training. Even though the data augmentation alleviates the class imbalance problem, i.e., improving the positive example ratio from 0.1% to 10%, the imbalance problem still exists. Therefore, we employ the classical weighted over-sampling algorithm on positive pairs to further reduce the imbalance effect. Here, the weights of the original positive examples in \mathbf{P} are set to 1 and pseudo positive examples’ weights are computed by $\mathcal{G}(\cdot)$ in Section 4.2. Here, since the dropout datasets are usually small compared to other Internet scaled datasets, we choose to use Gradient Boosting Decision Tree⁴ (GBDT) [16] as our prediction model. The GBDT exhibits its robust predictive performance in many well studied problems [24, 48].

4.4 Summary

The overall model learning procedure of our K-12 online dropout prediction can be summarized in Algorithm 1.

5. EXPERIMENTAL EVALUATION

In this section, we will (1) introduce our dataset that is collected from a real-world K-12 online learning platform and the details of our experimental settings (Section 5.1); (2) show that our approach is able to improve the predictive performance when compared to a wide range of classic

Algorithm 1 Model learning procedure of the K-12 online dropout prediction.

INPUT:

- A set of K-12 students \mathbf{S} and their corresponding multimodal classroom recordings and activities logs.
- The length of lookback window Λ .
- The choice of weighting function $\mathcal{G}(\cdot)$.

PROCEDURE:

- 1: // Feature extraction
- 2: Extract in-class features from multimodal recordings, see Section 4.1.1.
- 3: Extract out-of-class features from student activities logs, see Section 4.1.2.
- 4: Extract time-variant features, see Section 4.1.3.
- 5: Concatenate three types of features above.
- 6: // Label generation and augmentation
- 7: Create original positive and negative training pair sets, i.e., \mathbf{P} and \mathbf{N} , see eq.(1).
- 8: Generate the augmented pseudo positive training sets, i.e., $\tilde{\mathbf{P}}$ and the corresponding weights, see eq.(3).
- 9: // Model learning
- 10: Conduct weighted over-sampling on the union of \mathbf{P} and $\tilde{\mathbf{P}}$.
- 11: Train the GBDT model on the over-sampled positive examples and original negative examples.

OUTPUT:

- The GBDT dropout prediction model Ω .
-

baselines (Section 5.2); (3) evaluate the impacts of different sizes of lookback windows, different weighting functions in data augmentation and feature combinations (Section 5.3, Section 5.4 and Section 5.5); and (4) deploy our model into the real production system to demonstrate its effectiveness (Section 5.6).

We would also like to note that hyper parameters used in our methods are selected (in all experiments) by the internal cross validation approach while optimizing models' predictive performances. In the following experiment, we set the size of lookback window to 7 and the impact of window size is discussed in section 5.4. We choose to use the convex weighting function when conducting pseudo positive data augmentation.

5.1 Experimental Setting

5.1.1 Data

To evaluate the effectiveness of our proposed framework, we conduct several experiments on a real-world K-12 online course dataset from a third-party online education platform. We select 3922 registered middle school and high school students from August 2018 and February 2019 as our samples. All the features listed in Section 4.1 are computed and extracted from daily activity logs on the platform. In our dataset, 634 students choose to drop the class and the dropout rate is 16.16%. The average time span of the students on the platform is about 86 days, which provide us 338428 observational $\langle \text{student}, \text{time stamp} \rangle$ sample pairs in total. We randomly select 80% of students and use their corresponding $\langle \text{student}, \text{time stamp} \rangle$ sample pairs as training set and the remaining 20% of students' sample pairs for testing propose. The data augmentation technique discussed in Section 4.2 is only applied in training set.

5.1.2 Multi-step Ahead Prediction Setting

To fully examine the dropout prediction performance, we evaluate the model's predictions in terms of different multi-step ahead time spans, i.e, given a current timestamp, we predict the outcome (dropout or non-dropout) in the next X days, where X ranges from 1, 2, \dots , 14.

5.1.3 Evaluation Metric

Similar to [18, 50, 17, 15, 51, 21], we evaluate and compare the performance of the different methods by using the Area Under Curve (AUC) score, which is the area under the Receive Operating Characteristic curve (ROC) [14]. An ROC curve is a graphic plot created by plotting the true positive rate (TPR) against the false positive rate (FPR). In our dropout prediction scenario, the TPR is the fraction of the "at-risk" predicted students who truly drop out. The FPR is the ratio of the falsely predicted "dropout" students to the true ones. The AUC score is invariant to data imbalance issue and it does not require additional parameters, for models comparisons. AUC score reaches its best value at 1 and the worst at value 0.

5.1.4 Baselines

We compare our proposed approach with the following representative baseline methods: (1) Logistic Regression (LR) [28], (2) Decision Tree (DT) [46] and (3) Random Forest (RF) [22]. LR, DT and RF are all trained on the same set of features defined in Section 4.1 with our proposed method. The training set is created by using eq.(1).

5.2 The Overall Prediction Performance

The results of these models are shown in Figure 4. As we can see from the Figure 4, we have the following observations:

Figure 4: The overall prediction performance with different multi-step ahead time spans in terms of AUC scores.

- First, our model outperforms all other methods in terms of AUC scores on different future time spans, which demonstrates the effectiveness of our approaches with positive data augmentation. By adding more diverse pseudo positive training pairs with the corresponding decaying confidence weights, the GBDT model is able to learn the dropout patterns from multiple factors.

- Second, as we increase the lengths of time spans of multi-step ahead prediction, all the models' performances decrease accordingly. Our approach achieves AUC score of 0.8262 in the task of next day prediction while the performance downgrades to 0.7430 in the next two-week prediction task. We believe this is because of the truth negative mistakes the models make, i.e., the model thinks the students will continue but they drop classes in next two weeks. This indicates that without knowing more information from the students, the ML models have very limited ability in predicting the long-term outcomes of student status, which also reflects the fact that there are many factors that could lead to the dropouts.
- Third, comparing LR, DT, and RF, we can see, the DT achieves the worst performance. This is because of its instability. With small number of training data, the DT approach suffers from fractional data turbulence. The RF approach remedies such shortcomings by replacing a single decision tree with a random forest of decision trees and the performance is boosted. Meanwhile, as a linear model, the LR is not powerful enough to accurately capture the dropout cases.

5.3 Impact of Sizes of Lookback Windows

As we can see, the number of augmented positive training pairs is directly determined by the size of lookback window Λ . Therefore, to comprehensively understand the performance of our proposed approach, we conduct experimental comparisons on different sizes of lookback windows. We vary the window size from 3, 7, and 14. Meanwhile, we add a baseline with no data augmentation. The results are shown in Figure 5.

From Figure 5, we can see that the size of lookback windows has a positive relationship on AUC scores with the length of time span in multi-step ahead prediction. When conducting short-term dropout predictions, models trained on data augmentation with smaller size of lookback window outperform others. As we gradually increase the time span of future predictions, the more the model looks back, the higher the prediction AUC score it achieves. Overall, the model trained with 7-day lookback window has the best performance across different multi-step ahead time spans in terms of AUC scores.

5.4 Impact of Different Weighting Functions

In this section, we examine the performance changes by varying the forms of weighting functions. More specifically, we compare the prediction results of using the convex function to results of the other choices. The results are shown in Figure 6. As we can see from Figure 6, the convex option outperforms other choices by a large margin across all different multi-step ahead time spans. When computing the over-sampling weights of pseudo training examples, the convex function gives more weights to the most recent examples, i.e., examples close to the timestamp of true dropout observations. This also confirms the necessity of considering the recency effect assumption (Assumption 1) when building the dropout prediction framework.

5.5 Impact of Different Features

Figure 5: Models trained on data augmented by different size of lookback windows with different multi-step ahead time spans in terms of AUC scores. *none* represents the model training without any lookback data augmentation.

In this subsection, we systematically examine the effect of different types of features by constructing following model variants:

- In: only the in-class features are used.
- Out: only the out-of-class features are used.
- Time: only the time-variant features are used.
- In+Time: it eliminates the contribution of *Out* features and only uses features from *In* and *Time*.
- Out+Time: it eliminates the contribution of *In* features and only uses features from *Out* and *Time*.
- In+Out: it eliminates the contribution of *Time* features and only uses features from *In* and *Out*.
- In+Out+Time: it uses the combination of all the features from *In*, *Out* and *Time*.

Meanwhile, we also consider different multi-step ahead prediction settings, i.e., next 7-day prediction and next 14-day prediction and the prediction results are shown in Table 2. From Table 2, we observe that (1) by considering all three types of features individually, the model trained from *Out* features yields the best performance. Moreover, when comparing *In*, *Out* to *In+Time*, *Out+Time*, we obtain the significant performance improvement by adding *Out* features. These indicate the fact that dropout prediction for K-12 online scenarios are very different from MOOC based dropout prediction. The out-of-class activities and the quality of the service play an extremely important role in the prediction task; and (2) by utilizing all the sets of features, we could be able to achieve the best results in both prediction tasks.

Table 2: Experimental results of different types of features and different lengths of multi-step ahead time span in terms of AUC scores.

	In	Out	Time	In+Time	Out+Time	In+Out	In+Out+Time
Multi-step ahead time span - 7 day	0.6249	0.7764	0.6992	0.7145	0.7759	0.7768	0.7774
Multi-step ahead time span - 14 day	0.6251	0.7386	0.6766	0.6932	0.7393	0.7420	0.7430

Figure 6: Models trained on data augmented by different choices of weighting functions with different multi-step ahead time spans in terms of AUC scores.

5.6 Online Performance

We deployed our at-risk student warning system in the real production environment on a third-party platform between February 2nd, 2019 to April 1st, 2019. To watch the system performance in practice, we conduct the next-day prediction task where the system predicts the dropout probability for each on-going student at 6 am in the morning. All the students are ranked by their dropout probabilities and the top 30% of students with highest probabilities are marked as at-risk students. At the end of each day, we obtain the real outcome of all the students who drop the class. We conduct the overlap comparison between the predicted top at-risk students (30% of total students) and the daily dropouts and we are able to achieve that more than 70% of dropout students are detected by the system.

6. CONCLUSION

In this paper, we present an effective at-risk student identification framework for K-12 online classes. Compared to the existing dropout prediction researches, our approach considers and focuses on the challenging factors such as multiple modalities, length variability, time sensitivity, class imbalance problems when learning from real-world K-12 educational data. Our offline experimental results show that our approach outperforms other state-of-the-art prediction approaches in terms of AUC scores. Furthermore, we deploy our model into a production environment and we are able to achieve that more than 70% of dropout students are detected by the system. In the future, we plan to explore the opportunity of using deep neural networks to capture heterogeneous information in the K-12 online scenarios to enhance

the existing prediction pipeline.

7. ACKNOWLEDGMENTS

The authors would like to thank Nan Jiang from Peking University and Lyu Qing from Tsinghua University, for their contributions to this research during their internship in TAL Education Group.

ABSTRACT

Spatial visualization skills are essential and fundamental to studying STEM subjects, and sketching is an effective way to practice those skills. One significant challenge of supporting practice using sketching questions is the vast number of possible mistakes, making it time-consuming for instructors to provide customized and actionable feedback to students. The same challenge persists for computer programs as well. This paper introduces a clustering model designed to categorize sketching answers based on the severity and characteristics of their mistakes. The model is designed to be used by a computer-based training platform to provide customized, actionable formative feedback to students in real-time. The promising results also suggest a new and comprehensive set of evaluation criteria to assess a student's performance on sketching questions. As a broader contribution, our work is a proof-of-concept for a modeling approach to automatically evaluate and provide formative feedback on complex free-hand sketches using abstract features that may be generalized to a variety of disciplines that involve the creation of technical drawings.

Keywords

Automatic grading, Sketching, Clustering, Spatial Visualization, Formative feedback

1. INTRODUCTION

Spatial visualization is the ability to represent and mentally manipulate two-dimensional and three-dimensional objects [11]. A body of research has shown that good spatial visualization skills help students succeed in STEM education [39, 3, 13, 25, 27, 32, 41, 44]. It is encouraging that existing research also demonstrates that spatial visualization skills are malleable and can be trained and improved, for example, via forms of workshops and seminars [42]. There have been successes in increasing the retention rates of STEM freshmen students with spatial visualization skills training in recent years, especially for minority groups such as female

students [39, 23].

Besides multiple-choice questions that are traditionally used in spatial visualization training, free-hand sketching on grid paper is an effective type of practice question [38]. Sketching questions can imitate the sketching tasks required in many engineering disciplines, which is particularly helpful since sketching is a fundamental skill for engineering designs [22]. In the training process, since students gain from learning from their mistakes instead of failing in the first try and giving up based on the immediate-feedback assessment technique [26], students can benefit from having a second chance on a practice problem. However, providing formative feedback while not giving away the answer, which is known to support self-regulated learning [28], on free-hand sketching can be challenging due to the wide variety of possible incorrect answers on such activities.

While human instructors possess the capability to analyze an erroneous free-hand sketch, identify the source of potential errors and provide formative feedback, it is a time-consuming process and providing such feedback to a large student population would require prohibitive efforts that would likely prevent the feedback from being provided in a timely fashion [2]. Computer-based systems able to provide timely formative feedback can be considered as an alternative to address this limitation. However, one significant challenge to automatically providing immediate customized feedback for sketching questions is the need for a computer-based system to be able to recognize and understand how much an answer is different from the answer key and the types of mistakes students are making.

On the one hand, sketching questions have an enormous number of possible incorrect answers, which are often specific to a unique problem, making it difficult, if not impossible, to identify every possible error and to prepare unique feedback for each one. As an alternative, a computer-based system could be designed to recognize categories of answers based on the severity or characteristics of their errors and provide feedback relevant to each one. However, to the best of our knowledge, there is no existing research that categorizes answers to complex sketching questions based on their errors, either conceptually or computationally. The lack of solution motivated us to identify patterns that exist in students' erroneous sketching answers and create a computer-based algorithm that can categorize them in real-time.

Tiffany Wenting Li and Luc Paquette "Erroneous Answers Categorization for Sketching Questions in Spatial Visualization Training" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 148 - 158

Due to the lack of existing categories of erroneous answers in free-hand sketching problems, we propose the use of a clustering approach to identifying such categories. Our research questions are the following:

- RQ1 What categories exist in students' sketching answers based on the severity and characteristics of their errors?
- RQ2 How meaningful are the identified erroneous answer categories, and what actionable feedback can be provided for each category?

We constructed a list of features that can be used to characterize students' erroneous sketching answers. Using a k-mean clustering approach, we discovered six common answer categories for incorrect sketches that are distinct from one another according to the severity and characteristics of the errors. Our clustering results suggest a new set of evaluation criteria for complex free-hand sketching answers that is more interpretable and generalizable than those in prior work [7, 43, 5]. Also, we provide initial suggestions for the kinds of formative feedback appropriate for each answer category without giving away the answer [36].

To the best of our knowledge, our study is the first to identify categories of erroneous sketches, both computationally and conceptually, in spatial visualization sketching problems using abstract features. Our approach also has the potential to be generalized to other subject areas that require sketching practices, mostly technical drawings in various Engineering and Science subjects, such as circuit diagrams in Electrical Engineering, engine models in Mechanical Engineering, building plans in Architecture, and structural formula in Organic Chemistry.

2. RELATED WORK

2.1 Spatial Visualization Skills and Sketching

Spatial visualization skills were estimated to play an important role in 84 careers [37], most of which are STEM-related. A longitudinal study showed that psychometrically-assessed spatial ability predicts career in STEM fields after accounting for Math and Verbal aptitudes [45].

Spatial visualization skills are applied in various STEM areas. Research shows that students with better spatial visualization skills perform better in Chemistry [32, 6]. In Organic Chemistry, for example, students with strong spatial visualization skills draw preliminary figures more often. Hence they use figures to gain a better understanding of the questions and are more likely to answer them correctly [32]. Another body of research revealed the connection between spatial skills and Geoscience [17, 30]. In particular, students with strong visual penetration ability, e.g., imagining cross-sections, perform better in Geology [17]. Furthermore, understanding cross-sectioning is a basic skill in many other engineering subjects [9, 12]. Spatial visualization is also found to be tightly related to performance in Anatomy in Biology [34], Radiology in Medicine [16].

A wide variety of empirical research has shown that spatial visualization skills are malleable. Interventions designed

to improve spatial visualization skills reach, on average, a medium effect size of 0.47 [42]. A well-known training developed by Sorby (2009) showed significant post-test improvement for each class of college students over a 6-years-long study. In particular, Sorby found that the training significantly improved female students' retention rate but not that of male students [39]. The finding suggested the critical role of spatial visualization skills training in increasing the diversity of STEM field students.

Sketching ability is fundamental to engineering design [22] and highly correlates with many STEM subjects [35]. To improve spatial visualization skills, sketching is one of the most effective approaches [38]. Electronic sketching has also demonstrated potential in training spatial visualization skills [8, 47]. Thus, the application of sketching practice is worth studying for better improving spatial visualization skills.

2.2 Computer-based Evaluation and Formative Feedback for Sketches

To the best of our knowledge, there is no prior work on the evaluation of sketches in spatial visualization training, both conceptually or computationally. The use of computer-based formative feedback for spatial visualization sketching has not been studied either. There is a body of research on computer-based evaluation and formative feedback for other types of sketches [5, 7, 43, 40, 15, 18, 19, 20]. However, some of them are too simple or too domain-specific to be generalized to a complicated case as in spatial visualization sketches. Others' evaluation methods cannot provide actionable or easy-to-interpret formative feedback.

For free-hand sketching that is evaluated mostly based on the shape and structure, there are a few existing evaluation approaches in domains other than spatial visualization training. Bhat (2017) developed Skechography, a river-sketching auto-grading tool for Geology [5]. This tool could perform sketch recognition and compare the river's shape similarity using the Shape Context algorithm, the distances of start points and endpoints between a student's answer and the answer key. Based on the degree of similarity and distances, the tool provided a score that was a weighted sum of these three features. Skechography evaluated a river, which had only one line with specific features of a start point, an endpoint, and the shape of the line. The simplicity of this application has a weak external validity and cannot be used in evaluating spatial visualization sketches.

The work by Chandan et al. (2018) [7], on the other hand, worked on a complicated case of free-hand drawing of objects of specific categories, e.g., a bee, an airplane, etc. They applied a Convolutional Neural Network approach for object categorization and a Scale Invariant Feature Transform approach to check the similarity between a given sketch and the "standard" sketch. As feedback, the tool showed the percentage of similarity to various categories of objects. The use of deep learning methods made the interpretation of results challenging. Hence, this approach is limited in its capability to generate specific and actionable feedback to help students improve their answers.

Mechanix, a sketch-based tutoring system for learning forces applied on a truss, could provide specific feedback to free-

hand sketching of forces [43]. In this case, the errors that could occur were known and clearly defined on an arrow-basis. Given the small number of arrows, it is relatively easy to cater specific and actionable feedback to each error. In the case of spatial visualization sketches, a sketch contains far more number of lines, making it infeasible to provide a piece of feedback for each line.

There exists another body of work that focused on the recognition of East Asian characters, which are similar to a simple sketch [40]. However, these solutions applied an "all or nothing" approach to recognize the structure of a character, which was not helpful in providing specific formative feedback. A few other works aimed to evaluate and provide feedback on the quality or aesthetics of a sketch, but not on the correctness in terms of the structure of shape [15, 18]. There is also an evaluation approach for computer-aided design solid models specifically, using criteria related to parameters set in the computer-aided model, which does not apply to free-hand sketching because the concept of parameters is not intuitive in free-hand sketching [19, 20].

Overall, there is limited work on a computer-based evaluation of complex free-hand sketching based on structural correctness that can generate specific and actionable formative feedback. Our work aims to fill in this gap.

2.3 Answers Categorization in Content-based Automated Evaluation

In evaluating constructed response automatically from a content-based perspective, there is a rich body of work in evaluating short answer questions for a variety of subjects and domains [24]. However, except for the studies mentioned in the last section, there is very few existing literature related to the content-based evaluation of complex free-hand sketching. Therefore, we draw our inspiration from the existing research in evaluating short answer questions and apply it to complex free-hand sketches, a different type of constructed response.

Answer categorization is one of the most frequently used approaches to perform a content-based evaluation of short answers. In most cases, supervised learning is applied using a manually labeled training set based on pre-defined rubrics [21, 33, 1, 10, 29]. For example, c-rater applied NLP techniques that determined whether an answer contained each key concept and was widely applied on short answer questions in Biology, Psychology, Math, and Reading, to not only grade but to provide specific real-time feedback [21, 1]. Pulman and Sukkari (2005) experimented with Inductive Logic Programming, Decision Tree and Naive Bayes to classify short answers into the desired category for Biology [33].

In our case, however, there are neither pre-existing robust rubrics as the evaluation standard for spatial visualization sketches nor known categories of error. This brought difficulties to label a training set manually accurately. Also, most content-based evaluation approaches only provided up to three levels of scoring. Some exceptions that provided more than three levels of scoring were either unclear about the definition of the levels or the levels were only mechanical composition of the correct answer [24]. As an alternative,

Figure 1: Free-hand sketching tool for isometric sketching on the online spatial visualization training platform

we turned to unsupervised learning to perform answer categorization to identify categories that were as granular yet meaningful as possible. Clustering is an often-used unsupervised learning approach in short-answer grading, especially in the case of answering open-ended questions. Previous work [4, 48] has shown that clustering could group answers that are similar in text characteristics, semantics, and topics. Our work aims to leverage this method to categorize complex sketches in spatial visualization training.

3. METHODS

3.1 Data Collection

We collected data from students solving free-hand sketching problems in a 100-level engineering course called "Spatial Visualization" that utilized an online training platform over half a semester in Fall 2019 at our home institution, a large public university in the Midwestern United States. The online training platform was previously developed as a computer-based spatial visualization training platform [47] to enable practicing at scale using online exercise and automatic grading. Previous work has shown a significant improvement in spatial visualization skills for those who completed the exercises on the platform [47].

Students in the course met once a week in-person for an hour, and the majority part of the course was working through practice problems on the platform on their own as their weekly assignment, given the instructions. The focus of practice questions each week was different, depending on the particular set of skills that were being trained, such as mental rotation, cross-sectioning, and coded plan. The platform supports both multiple-choice questions and sketching questions. Figure 1 and Figure 2 show the free-hand sketching tool on the platform that allows students to sketch out their answers on the computer. Students can draw and erase lines on the grid paper freely. Students could also save their sketch when they leave the platform and load what they saved when they come back. In the course, students were given a maximum of two attempts for each sketching question, i.e., they were given a second chance if they answered incorrectly in the first attempt. All the sketching questions were graded with an "all or nothing" approach.

The collected dataset includes 370 incorrect sketches from 14 students in the course that covers five types of sketching questions and 61 unique questions. We excluded correct sketches in the categorization because they would naturally

Figure 2: Free-hand sketching tool for orthographic sketching on the online spatial visualization training platform

be in one category by mapping exactly to the answer key. Examples of the types of sketching questions include drawing the orthographic view of a 3D object given the isometric view or vice versa, and drawing the resulting 3D object after rotating a given 3D object with a certain degree in a given direction. Each type of sketching questions contained a series of different questions with 3D objects of various shapes. On average, each sketch contains approximately 30 to 80 lines of unit length.

Each submission of an attempt to answer a question produced a raw log describing their answer. In the raw log, two major types of information were recorded. First, it contained the set of lines in the final submitted sketch. Second, it recorded the history of all the timestamped steps a student took of adding or deleting a line, clearing, or loading the sketch for that question (Figure. 3). In this paper, we focused on the final submitted sketch only since the goal is to categorize the final answer instead of analyzing students' process of solving a free-hand sketching problem.

Each final submitted sketch is represented by the X-Y coordinates of a list of lines. The lines are further denoted by the type of the lines, either solid line or dashed line, which are the two standard types of lines used in the sketching exercise for different purposes. A sketch is mostly made up of solid lines, but a dashed line should be used instead of a solid line to represent a hidden edge from a particular perspective.

Another data point in the raw log is the type of grid paper used for a sketch. There are two types of grid paper in the sketching exercises: an isometric grid for isometric drawing, and a dot grid for orthographic drawing. A sketch is considered as correct only if the shape and the size of the object match with those of the answer key, and uses the correct type of grid paper. The position of where a sketch is drawn on the grid paper is flexible.

We performed two steps of data standardization on the raw log before feature extraction. First, we aligned both the student's answer and the answer key to the lower-left corner of the sketch-pad. Second, all the lines were broken down into unit length and de-duplicated so that lines that overlapped with each other would only be counted once. We conducted these two steps for the ease of comparing student's answers against the answer key.

3.2 Feature Extraction

Figure 3: An example of a raw log file generated from sketching questions on the online spatial visualization training platform

We developed a total of 8 features to use as input for our clustering model. We performed feature engineering manually after observing a small subset of the data to get an idea of what information human instructors might use when interpreting incorrect answers. In order to get a preliminary view of possible errors that would be as comprehensive as possible, we selected three questions that had the highest number of incorrect answers and observed the errors made by students on those problems. Based on our preliminary observation, we created three categories of features that represent different characteristics of the observed errors.

The first group of features uses a unit-length line as its basic unit, i.e., a line connecting adjacent points, and represents the number of lines that are wrong compared to the answer key. We observed from the subset of mistakes that the number of incorrect lines involved in a sketch varied widely, from only one wrong line to over 80% of lines being wrong. The number of incorrect lines is a straightforward way to quantify the degree to which a sketch was incorrect. We considered three scenarios in which a line is wrong.

1. **An extra line:** a line is in the student's answer, but there is no line at the same position in the answer key.
2. **A missing line:** a line is in the answer key, but there is no line at the same position in the student's answer.
3. **A line with incorrect type:** two lines with the same position in the student's answer and the answer key are of different types, i.e., solid line vs. dashed line.

To normalize the number of incorrect lines against the complexity of the sketch, we adopted the percentage of wrong lines instead of the absolute number, i.e., dividing by the total number of lines in a sketch. The three features in this group are Percentage of Extra Lines, Percentage of Missing Lines, and Percentage of Lines with Correct Position but Incorrect Type.

The second category of features represents the groupings of the incorrect lines based on their location in a sketch. In our preliminary observation, we found that, between two

Figure 4: An example of a sketch (on the right) with four error components, i.e., four sites of mistakes. The sketch on the left is the answer key.

sketches with a similar number of incorrect lines, the incorrect lines may be inter-connected and concentrated in one place in a sketch while being scattered in multiple spots in another sketch. These two cases represented the mistakes of different natures.

Based on the assumption that incorrect lines that are connected are more likely caused by the same mistake, we treated all the incorrect lines as an undirected graph and defined each component in the graph as one "site" of mistake. A component here has the same definition of a component in an undirected graph, a subgraph in which any two vertices are connected by paths, and which is connected to no additional vertices in the supergraph [46]. As an example, in Figure 4, there are a total of four error components in the sketch, three extra lines in different locations, and a disconnected taller stack separated from the bottom of the object.

We constructed three features in this category. The first feature is the number of components in the graph made of incorrect lines, which is a representation of the number of mistake sites in a sketch. Since the size of a component represents how severe a mistake is, the second feature is the average size of all the error components in a sketch. The larger the average component size is, the more severe the mistakes are on average. The last feature is the maximum size difference among all error components, which reflects the range of severity across multiple mistake sites in a sketch.

The last set of features describes the general characteristics of the sketch. One feature is whether the student uses the same type of sketching grid as the answer key. Another feature is whether the sketch is empty. If it is empty, it indicates either the student did not attempt the question or accidentally skipped the question.

3.3 Model Construction

As there was no prior framework or knowledge on how to categorize the erroneous sketches, it was not possible to obtain labels (ground truth) describing each answer. As such, we used an unsupervised clustering algorithm to identify categories of erroneous answers from existing data. Based on prior observation of the data, we hypothesized that the features of each cluster should have a sphere-like shape. Therefore, we used k-means clustering with squared Euclidean distance. The algorithm aims to assign all the data points into a specified number of clusters such that every data point is

Figure 5: Examples of mistakes in Cluster 0, having one minor mistake. The sketch on the left is the answer key.

in the cluster with the nearest mean. Ideally, data points that have similar values across all the features are grouped in one cluster.

After feature extraction, we performed further data normalization as the first step of model construction. Since the k-means clustering algorithm is sensitive to the scale of the features, we normalized each of the three features (Number of Components, Average Size of Components, and Maximum Difference between Size of All Components) into the unit interval respectively across all data, so that they were on the same scale as the other features that were either in percentages or in a boolean format.

We performed parameter tuning to decide on the optimal number of cluster k . We started with two clusters and repeatedly increased the number of clusters by one. We evaluated the choice of k using two criteria. The main criterion we used to evaluate the quality of the clustering results was how interpretable a new cluster was and whether it could help us provide more specific and actionable feedback. Another complementary criterion for evaluation was the Silhouette score, measuring the quality of the clusters based on the cohesion of the separation of the identified clusters (Silhouette score ranges from -1 to 1). We valued the interpretability of a cluster over a higher Silhouette score. Therefore, as long as the Silhouette score remained at an acceptable level, we increased k until the interpretation of the newly generated cluster did not make sense or did not differ much from the existing clusters.

4. RESULTS

Our clustering approach identified a set of six clusters related to categories of erroneous answers in free-hand sketching problems, as listed in Table 1. The 6 clusters are ordered based on the severity of the errors in the table. The clustering model yields a Silhouette score of 0.6659, which is a reasonable value.

Cluster 0 is the most common cluster in the dataset. From the centroid value, we can see that the sketches in this cluster only have one mistake (Number of Component = 1) with about two incorrect lines (Avg Component Size = 1.89). The centroid values suggested that a large portion of the errors had only one minor mistake, which was most likely due to drawing errors such as forgetting an edge at the corner, or drawing an extra edge on a plane (see examples in Fig 5).

Cluster 1, the second-largest cluster in the dataset, differs from Cluster 0 mainly by the number of mistakes in the sketch. On average, there are 2.21 mistake components in

Cluster ID	Cluster Size	Interpretation	Perc Missing	Perc Extra	Perc Type	Num Comp	Avg Comp Size	Max Size Diff	Same Grid?	Empty?
0	218	Have one minor mistake	2.39%	2.16%	0.04%	1.00	1.89	0.00	1.00	0.00
1	65	Have more than one minor mistakes	4.13%	10.46%	0.11%	2.14	2.88	1.43	1.00	0.00
2	30	Have both major and minor mistakes, mostly minor mistakes	20.61%	32.14%	0.29%	3.70	5.13	5.63	1.00	0.00
3	15	Have both major and minor mistakes, mostly major mistakes	37.82%	22.46%	0.77%	2.80	10.69	15.73	1.00	0.00
4	39	More than half of the sketch as a whole is completely wrong	80.08%	67.04%	0.00%	1.05	45.35	0.08	1.00	0.00
5	3	Empty sketch	100.00%	0.00%	0.00%	1.67	29.78	1.00	0.33	1.00

Table 1: Clustering Results Summary Table: The size, interpretation and centroid of each cluster are shown in the table. The centroid values are transformed back to its original scale if unit normalization was performed. Values are color-coded with different shades of red, representing low values to high values)

Figure 6: Examples of mistakes in Cluster 1, having multiple minor mistakes. The sketches with a white background are the answer keys.

the sketch. The average size of 3.04 lines of the components suggests that these are still minor mistakes with three incorrect lines on average. It is reasonable to interpret Cluster 1 as sketches that have several minor mistakes. Examples of this category are shown in the examples in Fig 6. Even though both Cluster 0 and Cluster 1 contain minor errors, they are different enough because students in Cluster 0 make one small mistake likely due to being careless. In contrast, those in Cluster 1 may have misconceptions that are causing a series of mistakes.

Cluster 2 and 3 are quite different from Cluster 0 and Cluster 1. Both of them have a much higher Percentage of Missing Lines and Percentage of Extra lines compared to Cluster 0 and 1, suggesting more severe mistakes in the sketch. More severe errors are more likely to be due to an incorrect structure at specific parts of the sketch rather than careless mistakes. These two clusters both have a high number of components (3.70 and 2.80 for Cluster 2 and 3 respectively), suggesting a series of mistakes across the sketch. Cluster 2 and 3 are different in two perspectives. First, Cluster 2's average component size is small (5.13), while Cluster 3's average component size is a lot bigger (10.69). Second, Cluster 3 has a massive difference in size across the different components (15.73), while Cluster 2 has a medium difference of 5.63. These differences suggest that within the series of mistakes in a sketch in Cluster 2, more of them are minor,

Figure 7: Examples of mistakes in Cluster 2, having multiple minor mistakes and a small number of major mistakes. The sketches with a white background are the answer keys.

and there is only a small proportion of major mistakes, as shown in Figure 7. On the other hand, a sketch in Cluster 3 has mainly major mistakes and fewer minor mistakes, as shown in Figure 8. The major mistakes in Cluster 3 are also more severe than those in Cluster 2 on average.

Cluster 4 has 80% of the lines missing and 67% extra lines, a lot higher than the previous clusters. Interestingly, most of the sketches in this cluster have only one component in their mistake (1.05 components on average), with an average size of 45.35 lines. These features suggest that there is one substantial mistake that spans over half of the sketch, which is often due to either an utterly wrong structure or a wrong orientation. For example, both examples in Fig 9 have the correct structure but wrong orientations.

Lastly, Cluster 5 contains empty answers, either due to the student not attempting a question or accidentally skipping it. Even though the cluster size is small, with only 3 data points due to the low number of empty answers, it is distinct enough from all the other clusters to be on its own.

Overall, we considered the erroneous answer categories detected to be intuitive and well-defined. They are distinct in the severity and characteristics of the mistakes. Being able

Figure 8: An example of mistake in Cluster 3, having multiple major and minor mistakes, but mainly major mistakes. The sketch on the left is the answer key.

Figure 9: Examples of mistakes in Cluster 4, having one huge cluster of mistake. The sketch with a white background is the answer key.

to automatically identify six categories of erroneous answers demonstrated the potential advantage of using an unsupervised approach in answer categorization than a supervised learning approach that tries to align the model capability with human judgment of the answer categories, which could often only yield up to three clearly defined categories [24]. Additionally, we did not observe any significant difference between the frequency distribution of the error categories across the different types of questions in our dataset, i.e., the frequency of each answer category did not differ significantly across all five types of sketching questions, suggesting the generalizability of the error categories to more variety of questions.

5. DISCUSSION

5.1 Evaluation Criteria for Sketching

Due to the lack of prior work on erroneous answer categories in complex free-hand sketching problems, there is no currently available set of criteria to evaluate the degree of correctness of a complicated sketching answer. In multiple offerings of the spatial visualization training in the past in our school, an instructor either used an "all or nothing" evaluation approach, or used a subjective standard on one or two dimensions to judge a sketch, e.g., taking off 0.5 point for each missing or extra line up to a maximum of 1 point, taking off 1.5 points any time when not all features of the top, front, and right sides are correct. These evaluation schemes are too coarse to reflect the degree of correctness of a sketch accurately. The results of our clustering analysis provide promising results towards the development of a more comprehensive view on how to evaluate a sketch using a scale of multiple levels.

Our model demonstrated that more than one dimension is needed concurrently to provide a nuanced interpretation of the state of a sketch. In our model, the percentages of missing, extra lines or lines with the wrong type, the number of mistakes sites, the average size of the mistakes, and how different the various mistakes sites are in a sketch are used in combination with one another to determine the degree of correctness and the type of errors. For example, a distinction between Cluster 2 and 3 suggests that with a similar percentage of incorrect lines, the number of mistakes components and the average size of the components brings additional insights into whether a sketch contains a large number of minor mistakes or a small number of major mistakes. As another example, even though Cluster 0 and Cluster 1 have a similar average size of mistakes, the number of mistake sites suggests that students in Cluster 1 may have a more systematic misconception than those in Cluster 0 who likely commit a mistake due to carelessness.

Our approach could also be used to define minor mistakes versus major mistakes in a sketch for a group of sketching questions with similar size and complexity. Without a systematic review of all the mistakes in a group of sketching questions, it is hard for an instructor to draw an objective line between an error that is significant and one that is not. As a result, the evaluation criteria may be overly strict or overly generous. The clustering model computationally categorizes what it considers as minor and major mistakes based on the optimal separation principle. Its outcome can serve as analytical support for an instructor's grading decision.

5.2 Potential Intervention

Since one of the motivations to construct this model is to provide real-time, customized, and actionable formative feedback, we propose potential customized intervention messages for each erroneous answer category. Based on the best practices of offering formative feedback [36], each of the messages follow a similar structure of (1) first letting the student know how far they are from the correct answer, (2) describing what types of mistake there are, and (3) suggesting ways for the student to approach solving the errors. A summary of the interventions is provided in Table 2.

Students having answers that fall into Cluster 0 or Cluster 1, which consist of having one or more minor errors, understand what the object should look like structure-wise. When the system tells them that they are wrong, they may find it confusing since they are likely confident in their answer. Hence, the feedback message could first assure the students that they have got the general structure of the object correct. Then, the system could let the students know that they have X number of minor mistakes, where X is the feature Number of Components. The feedback may also include whether they have some missing lines, extra lines, or lines of the wrong type. Lastly, the feedback message would suggest the students check for details of their drawing by listing out the common reasons for such errors, such as extra edges on a flat plane, missing edges at a corner.

If the answer falls within Cluster 2 or Cluster 3, the feedback message should be different from that for Cluster 0 and 1 because there is at least one major mistake in the answer,

Cluster ID	Cluster Size	Interpretation	Potential Intervention
0	218	Have one minor mistake	<ul style="list-style-type: none"> Encourage students that they get the general structure correct Inform students the number of minor mistake sites they have Suggest students to check for detail errors and list the common reasons for such errors, e.g. extra edges on a flat plane, missing edges at a corner
1	65	Have more than one minor mistakes	
2	30	Have some major and minor mistakes, mostly <u>minor</u> mistakes	<ul style="list-style-type: none"> Encourage students that they are heading towards the right direction Inform students the number of minor and major mistake sites they have Suggest students to revisit some parts of the structure Suggest students to carefully check for drawing errors and list the common reasons for such errors, e.g. extra edges on a flat plane, missing edges at a corner
3	15	Have some major and minor mistakes, mostly <u>major</u> mistakes	
4	39	More than half of the sketch as a whole is completely wrong	<ul style="list-style-type: none"> If students have the correct structure but a wrong orientation: <ul style="list-style-type: none"> Encourage students that they get the general structure correct Inform them that they may have drawn it in an incorrect orientation If students have an incorrect structure: <ul style="list-style-type: none"> Let students know that they have the wrong idea for the structure Suggest students to rethink about the structure from the beginning Provide hints for the students if available
5	3	Empty sketch	<ul style="list-style-type: none"> If students did not make an effort, encourage them to attempt the question If students forgot to submit a sketch, remind them to submit in the next attempt

Table 2: Interventions Summary Table

likely due to a structural error. The students in these two cases are mostly on the right track in terms of the general structure of the sketch. Hence, the feedback message could first encourage them that they are heading in the right direction. The system could then say that the sketch has X minor mistakes and Y major mistakes, where X is the Number of Components with a size smaller than the Average Component Size of the cluster centroid, and Y is the Number of Components with a size larger than the average. Finally, the intervention message could suggest the student first revisit the structure in detail to identify the major mistake, and then carefully check for drawing errors referring to a list of common minor mistakes.

For a student that falls into Cluster 4, it is likely that the student is either on the wrong track entirely or uses a wrong orientation. The system can perform a further check to compare the student's answer to other possible orientations and see if it belongs to the case of having a wrong orientation. If it is, the feedback message will remind the student that the structure of the sketch is mostly correct, but the orientation is incorrect. If it is not the case of having a wrong orientation, the feedback message will remind the students that they may have the wrong idea for the sketch, and they should reconsider the question from the beginning. The system could consider providing hints to the students as well in this case.

Lastly, if a student submits an empty sketch, the system can check the time spent on the question to determine whether the student did not attempt the question at all or forgot to click the submit button. If the student did not attempt the question, the system would encourage the student to make an effort in attempting to solve the problem. If the student forgot to submit the answer, the feedback message would

remind them to submit in the next attempt.

5.3 Generalizability of the Proof-of-concept Approach

Our clustering model is more than a single model that works only in a specific scenario. It is a proof-of-concept approach for the evaluation of a complex free-hand sketch based on abstract features. Our contributions to the evaluation scheme of sketching answers have the potential to be generalized from spatial visualization training to more fields that involve free-hand technical drawings in various Engineering and Science subjects, such as circuit diagrams in Electrical Engineering, engine models in Mechanical Engineering, building plans in Architecture, and structural formula in Organic Chemistry. Technical drawing is similar to spatial visualization sketching in the sense that they both follow strict rules of sketching and are often drawn on grid paper to ensure a consistent proportion and orientation. Technical drawings in these fields usually start from a fundamental practice of drawing and modeling using practice problems that have a limited number of correct answers. With the presence of answer keys, our unsupervised clustering approach is flexible and easy to be retrained on new datasets to adapt to new types of sketches, even with additional features developed based on the learning goal of the type of sketches.

On the other hand, for technical drawing that involves a creative component or pure creative drawing, it may be harder to apply our approach directly. In evaluating creative drawing that does not have a limited number of correct answers, a mistake may be more subjective, and the evaluation may extend beyond getting a sketch correct to being functional, optimal, creative or aesthetic. The clustering approach based on abstract features of a sketch, however, may be used for

other purposes in this case. For example, our approach could be used to group sketches with similar characteristics together for the convenience of human graders, especially in a large course with limited human resources, such as Massive Open Online Courses. Reconsideration in feature engineering would be needed to achieve the new goals.

6. LIMITATIONS AND FUTURE WORK

The current erroneous answer categories do not take into account specific reasons that lead to a particular error in an answer. There may be multiple reasons for a student to end up with mistakes in the same category. To the best of our knowledge, there is neither prior work that studies the common misconceptions in spatial visualization sketching, nor cognitive models that describe the process of this task. The closest available work in cognitive models for spatial ability focuses on how people solve multiple choice spatial visualization questions, i.e., when candidate solutions are provided [14, 11, 31]. These models do not cover the process of generating a spatial object from scratch, which is what sets spatial visualization sketching apart from the traditional spatial ability tests. Hence, our proposed model is unable to distinguish the errors by their causes. Future research conducting qualitative interviews with students to understand the reasons why an error occur could provide valuable insights towards identifying not only broad categories of erroneous answer, but also the causes behind various error categories. It would also be beneficial to create cognitive models to understand systematically the strategies students used to solve these problems. These information would be valuable in further developing other features that could distinguish errors according to their underlying cause, for example, by leveraging the temporal sequence of actions executed by the student leading to their error. Improving current models to include information about the most probable cause of an error would be beneficial in generating formative feedback that goes beyond providing information about the nature of the students' error, and integrates conceptual information to support students in addressing misconceptions.

The current training data for the model only involved 14 students, which is a relatively small sample. As such, the current model can be seen as a proof-of-concept for the feasibility of erroneous answer categorization. Applying the same approach to a larger population of students will be necessary to validate the stability of the model and ensure that there are no additional answer categories that may not have been included in our current dataset. Future studies can re-train and test the model on a larger population to confirm the existence of the answer categories identified within the current study. Since the training process of the model is simple, re-training the model based on another dataset would be straightforward.

Another next step for this research is to deploy the model in an online training platform and conduct user testing to examine the effectiveness and accuracy of the categorization and intervention. Last but not least, the method proposed in this study is designed to be flexible and be applied to other disciplines. Future work in other disciplines, such as evaluating circuit diagrams in Electrical Engineering, engine models in Mechanical Engineering, building plans in Architecture, and structural formula in Organic Chemistry, will

need to be conducted to evaluate the extent to which the proposed method generalizes to new topics.

7. CONCLUSION

In conclusion, this paper presents a clustering model as a solution to categorize erroneous answers in complex free-hand sketching questions in spatial visualization training. Eight abstract features were developed and proven to be effective in the categorization of erroneous answers, including percentages of various types of incorrect lines, number of mistake components, and metrics of the size of the components. The clustering model detected six answer categories based on the severity and scale of the mistakes. With these detected categories, an online training platform will be able to present customized and actionable formative feedback in real-time. Moreover, our approach suggested a new and comprehensive set of evaluation criteria to assess a sketch, which could potentially be generalized to other disciplines that require sketching practices.

ABSTRACT

Digital educational technologies offer the potential to customize students' experiences and learn what works for which students, enhancing the technology as more students interact with it. We consider whether and when attempting to discover how to personalize has a cost, such as if the adaptation to personal information can delay the adoption of policies that benefit all students. We explore these issues in the context of using multi-armed bandit (MAB) algorithms to learn a policy for what version of an educational technology to present to each student, varying the relation between student characteristics and outcomes and also whether the algorithm is aware of these characteristics. Through simulations, we demonstrate that the inclusion of student characteristics for personalization can be beneficial when those characteristics are needed to learn the optimal action. In other scenarios, this inclusion decreases performance and increases variation in student experiences. Moreover, including unneeded student characteristics can systematically disadvantage students with less common values for these characteristics. Our simulations do however suggest that real-time personalization will be helpful in particular real-world scenarios, and we illustrate this through case studies using existing experimental results in ASSISTments [23]. Overall, our simulations show that adaptive personalization in educational technologies can be a double-edged sword: real-time adaptation improves student experiences in some contexts, but the slower adaptation and increased variability mean that a more personalized model is not always beneficial.

Keywords: multi-armed bandits, personalization, educational technologies, online adaptive algorithms, simulation

1. INTRODUCTION

Within educational technologies, there are a myriad of ways to design instructional components such as hints or expla-

nations. Research in education and the learning sciences provides some insight into how to design these resources (e.g., [25, 3]). However, there is often uncertainty about which version of a resource will be most effective in a particular context, and effectiveness may vary based on students' characteristics, such as prior knowledge or motivation.

Randomized experiments are one way to compare multiple versions of a technology, but such experiments impose a delay between collecting required evidence and using that evidence to improve student experiences. Recently, multi-armed bandit (MAB) algorithms have been proposed to improve technologies in real time: each student is assigned to one version of the technology, and the algorithm observes the student's learning outcome [18, 28]. Each subsequent student is more likely to be assigned to a version of the technology that has been more effective for previous students, as the algorithm discovers what is effective. Such algorithms maintain uncertainty as they learn, balancing exploring to learn more about what works with exploiting the observed results from previous students. Typical MAB algorithms do not take into account student characteristics and thus can only identify which version of a technology is better for students on average, but contextual MAB algorithms can personalize which version to assign to each student, potentially increasing the number of students who are directed to versions that are most helpful for them individually [24].

While deploying contextual MAB algorithms could improve student experiences, it raises two potential issues. First, instructional designers must decide which student characteristics will be considered for personalization. For instance, more concrete examples might be more helpful for students with lower prior knowledge, while more abstract examples could be more helpful for students with higher prior knowledge. This relationship could only be learned if the algorithm has 'prior knowledge' as a feature of each student. Should the algorithm also consider which prerequisite course was taken when selecting an example, or is prior knowledge sufficient? Designers are unlikely to be certain which characteristics influence effectiveness, but the choice of characteristics will influence the performance of the algorithm. Excluding characteristics that do impact effectiveness could decrease the positive impact on students, but including extraneous characteristics that do *not* impact effectiveness could

Zhaobin Li, Luna Yee, Nathaniel Sauerberg, Irene Sakson, Joseph Jay Williams and Anna Rafferty "Getting too personal(ized): The importance of feature choice in online adaptive algorithms" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 159 - 170

also decrease this impact. In the latter case, the system might have to do more exploration to learn how the effectiveness of instruction differs along each extraneous characteristic, and so direct a greater number of students to less effective versions.

The second issue raised by online adaptive algorithms is whether the constantly adapting system will benefit certain groups of students more than others. Since contextual MAB algorithms learn by observing how the consequences of their choices are related to feature values, students whose characteristics are less common may be more likely to interact with the algorithm when it has limited information about what is most effective for that type of student. This could exacerbate differences in outcomes between subgroups of students. Yet, such algorithms could also have an equalizing effect for students with less common characteristics: students have the potential to experience a version of the technology that is most appropriate for them, even when this version is not the most appropriate for a typical student.

In this paper, we use simulations to explore these issues and their consequences for student experiences in adaptive educational technologies which use MAB algorithms. We focus on three common types of models for how student characteristics are related to outcomes: a *baseline* model in which student characteristics do not impact the effectiveness of different versions of the technology; a *universal optimal action* model, in which student characteristics impact effectiveness but the same version is most effective for all students; and a *personalized optimal action* model, in which student characteristics impact which version leads to the best outcomes for a given student.

We show that including the potential for personalization significantly degrades student outcomes except in the *personalized optimal action* model, where this information is necessary to encode the best policy. While the cost of including more characteristics for personalization is relatively modest, including these characteristics leads to greater variation: the algorithm is less consistent in learning which versions are best overall, and students may be systematically treated differently based on characteristics that do not influence their outcomes. This increased variance is worsened when student characteristics are not uniformly distributed, with some characteristics being more common than others. We use experimental data to show the potential benefits of personalization and add nuance to the prior simulation results by demonstrating how personalization can benefit not only students in a minority group but also all groups of students. We end by discussing the consequences of these results for integrating adaptive components into existing educational technologies.

2. RELATED WORK

A wide array of work has focused on using MAB and contextual MAB algorithms for optimization, including applications in advertising and recommendations (e.g., [17]), crowdsourcing (e.g., [14]), and designing experiments and clinical trials (e.g., [26]). Within educational technologies, MAB algorithms have been primarily used in two ways. Some work has used these algorithms to select problems that are of an appropriate difficulty level for a particular student [8,

16, 22]; unlike our work, these applications typically combine learned profiles about students with a second source of knowledge, such as prerequisite structure. We focus on a second proposed usage of MAB algorithms in education: assigning students to a particular version of a technology. For example, non-contextual MAB algorithms have been used to choose among crowdsourced explanations [27] and to explore an extremely large range of interface designs [19]. Some of this work has also considered the implications of collecting experimental data via MAB algorithms on measurement and inference [18, 20], showing systematic biases that can impair the drawing of conclusions about the conditions. Only a limited amount of work has applied contextual MAB algorithms to personalize which versions of a technology a student experiences (e.g., [24], but focused primarily on measurement). We build on this body of work by considering the performance implications of several common scenarios for how student characteristics, versions of an educational technology, and outcomes are related. Additionally, by specifically examining some scenarios in which student characteristics are unevenly distributed, we raise issues about personalization for minority groups of students.

There is a great deal of theory-based literature on both standard and contextual MAB algorithms related to quantifying performance, especially in terms of asymptotically bounding growth in cumulative regret (the amount that the expected reward from choosing an optimal action outpaces reward from the actually chosen actions). The optimal worst-case bound on regret growth is logarithmic [4]. Furthermore, the inclusion of contextual variables increases cumulative regret at least linearly; for Thompson sampling, which we use in our simulations, the regret bounds grow quadratically in the number of contextual variables [2]. We use simulations to consider non-asymptotic settings and focus on areas less explored theoretically, like impacts on individual groups of students and variability in performance.

In this paper, we are particularly concerned with how outcomes differ among different groups of students. One of the promises of educational technologies is to boost all students' outcomes to the level that can be achieved by individualized tutoring [9], and online adaptive algorithms may make it easier to develop such systems. Yet, the broader machine learning community has recently highlighted how automated systems can learn or exacerbate existing inequalities (see, e.g., [12] for an overview). Within educational data mining, there have been mixed results when the fairness of different models has been explored, and this variation has often been correlated with the diversity of the training data: [13] demonstrated that a model trained on a large and diverse dataset performed similarly well for predicting on-time graduation for students in different demographic groups, while [11] found disparities across genders in predicting course dropout, often associated with gender imbalances in the training data. This raises the issue of how to best use educational data mining in ways that promote equity across students. Within the MAB literature specifically, there has been limited discussion of fairness (e.g., [15]), although [21] show that a particular technical definition of data diversity can lead to fairer outcomes. Like in our work, [21] shows cases where the presence or absence of a majority group can help or harm minority group outcomes. Our work con-

siders scenarios specific to education, demonstrating that the particular scenario in [21] can be generalized considerably, and more precisely characterizes the circumstances in which including personal characteristics increases equity versus where doing so may lead to systematically poorer experiences for students in a minority group.

3. CONTEXTUAL MAB ALGORITHMS

We treat the problem of determining what version of an educational technology will be most effective for a student as a MAB problem. In such problems, a system must repeatedly choose among several actions, a_1, \dots, a_K . The system initially does not know which action is likely to be the most effective, but after each action choice, the system receives feedback in the form of a stochastic reward $r^{(t)}$.

There are a variety of MAB algorithms for choosing actions. We focus on Thompson sampling [1], which is a regret-minimizing algorithm that exhibits logarithmic regret growth. Thompson sampling maintains for each action a distribution over reward values. This distribution is updated after each action choice and represents the posterior distribution over reward values given the observed data. At each timestep, the algorithm samples from the posterior distribution over rewards for each action, and then chooses the action with the highest sampled value. While Thompson sampling is also applicable to real-valued rewards, many educational outcomes are binary, such as whether a student completes a homework assignment or answers a question correctly. Thus, we focus on these binary rewards in this paper, using a Beta prior distribution to enable simple conjugate updates after each choice.

In our setting in which we choose versions of an educational technology for each student, the actions are the different versions of the technology, and the reward is the student outcome. For example, imagine a student interacting with a system to do her math homework. The system might choose between two actions when the student asks for a hint: (a) show a fully worked example, versus (b) provide the first step of the problem as a hint and ask the student to identify an appropriate second step. The student outcome could be whether or not she completes the homework assignment.

In a traditional MAB problem, the reward distribution is fixed given the action choice. However, in the situation above, the reward may be dependent on the characteristics of the student. For instance, a student who has stronger proficiency in the prerequisite skills may be more prepared to identify what to do next in the problem, while a student with weaker proficiency may not be able to identify what to do next. A contextual MAB algorithm incorporates such student characteristics as features into its action choices.

For parametric contextual MAB algorithms, the features must be predetermined, including whether interactions between features is permitted. We adopt a contextual Thompson sampling approach that uses regularized Bayesian logistic regression to approximate the distribution of rewards given the features [2, 7]. The algorithm learns a distribution over the feature weights as coefficients using a Gaussian posterior approximation. To make each new action choice, the algorithm computes a reward value for each action by

sampling each weight independently. The chosen action is the action with the highest sampled reward value. Updates may occur after each action or in batches to decrease computational costs; because the feature vectors that we consider are relatively small, we update after each action.

4. IMPORTANCE OF FEATURE CHOICE

When using a contextual MAB algorithm to personalize student experiences in an educational technology, the system designer must choose which student characteristics to include as variables for personalization. The designer is very unlikely to know with certainty which student features are truly relevant and will actually impact student outcomes. One could include every possible relevant feature, knowing that while the algorithm can learn that an included feature is not relevant, it cannot learn that a non-included feature is in fact relevant. However, asymptotic growth rates for regret are quadratic in the number of features [2], meaning that as more features are included, the algorithm will tend to take longer to learn. Designers thus must balance the desire to include all features that influence outcomes with the knowledge that extraneous features could hurt performance.

To better understand how student outcomes are impacted by the choice of features for personalization, we systematically explore the inclusion of both relevant and non-relevant features in a contextual MAB algorithm and examine the impact on student outcomes and on the rate of assigning students to their personally optimal version of the technology. For these simulations, we assume that features are uncorrelated and that their values are chosen uniformly at random for each student, i.e., the probability of observing any particular combination of features is the same as observing any other combination of features.

4.1 Methods

4.1.1 Representing student features

We focus on binary student features and thus feature values implicitly group students. For example, some CS classes may have two different prerequisites, such as a discrete math course taught by the CS department or a similar one taught by the math department. Students who have taken the CS version will all have the same value for the prerequisite feature, while those who take the math one will have the other.¹

4.1.2 Outcome-generating models

The outcome-generating model describes the *true* relationship between student characteristics (feature values), the actions of assigning students to different versions of a technology, and the outcomes of student learning. We focus on scenarios in which two actions, such as choosing between concrete versus abstract explanations, affect the outcomes for two groups of students, such as those with math versus CS prerequisite as aforementioned.

In each of the models, we generate the true reward probability for a student with particular features using logistic regression, with a separate logistic regression equation for

¹In both the MAB algorithms and the outcome-generating models, feature values are represented using dummy variables.

Relevant Feature: Action Number:	F=0		F=1	
	A1	A2	A1	A2
Baseline	0.4	0.6	0.4	0.6
Universal optimal action (1)	0.4	0.6	0.6	0.8
Universal optimal action (2)	0.4	0.6	0.4	0.8
Universal optimal action (3)	0.4	0.6	0.5	0.7
Universal optimal action (4)	0.4	0.6	0.8	0.9
Personalized optimal action	0.4	0.6	0.6	0.4

Table 1: Reward probabilities for each combination of actions (A1 and A2) and values of the relevant feature (F=0 and F=1) in the simulations. The optimal action, shown in bold, is the same (A2) for both feature values, except for the personalized optimal action model.

each action. Given a feature vector $x^{(j)}$ for student j , the reward probabilities are generated according to:

$$P_{action=k}(\text{reward} = 1 \mid x^{(j)}) = \text{sigmoid}(b_{0,k} + \sum_{i=1}^n b_{i,k}x_i),$$

where b_k is the coefficient vector for action k and has intercept $b_{0,k}$. For our simulations, the coefficients for the feature values were zero for any feature past the first feature, meaning that a maximum of one student feature impacts the outcomes but more features may still be observed. By varying the coefficients for the intercept ($b_{0,k}$) and the first feature, we produced three models for the relationship among student characteristics (i.e., features or feature values), action choices, and outcomes (see Table 1):

- *Baseline*: Student features have no impact on outcomes.
- *Universal optimal action*: Student features have an impact on outcomes, but not the optimal action—the best version of the technology is the same regardless of features.
- *Personalized optimal action*: Student features impact outcomes, meaning that the optimal action differs based on features—some students are better off experiencing Version A of the technology while for others Version B.

For the baseline model, the coefficients of the actions vary only for the intercept in order to control the effect of each action when student features are ignored. For the universal optimal action model, we included four variations to capture different educationally meaningful scenarios. For instance, universal optimal action (1) reflects a case in which differences in prior knowledge minimally interact with the impact of different versions of a technological intervention, while (2) reflects a student characteristic magnifying the effectiveness of an intervention.

4.1.3 Simulation parameters

We varied three factors across the simulations: the outcome-generating model; the MAB algorithm (contextual or non-contextual); and the number of student features. For all simulations, we considered three horizons: classrooms of 50, 250, and 1000 students. Multiple horizons illustrate the behavior of the algorithm at different time points and can guide decisions for incorporating adaptive algorithms based on the number of students who are expected to interact with the system. Each simulation was repeated 1000 times.

For the non-contextual Thompson sampling, parameters for a Beta distribution per action are learned independent of student features. For the contextual algorithm, we specify the weights of the student features as model coefficients. All simulations included at least one student feature regardless of the outcome-generating models.

To model the fact that curriculum designers may not know which student characteristics really matter, we included simulations where the observed features were a superset of those that actually impacted outcomes. Specifically, we considered models with a total of 1, 2, 3, 5, 7, 8, and 10 features. Therefore, for the non-baseline scenarios, the proportion of included features that impacted outcomes varied from 100% to only 10%. Since our contextual features are binary, we include indicator variables for each of the two values, and learn a separate weight for each indicator variable.²

4.2 Results

First we focused on analyzing the performance of contextual and non-contextual MAB algorithms for the three outcome-generating models across 1 to 10 student features (i.e., contextual variables). Using an analysis of covariance (ANCOVA), we compared the two MAB algorithms' performance with respect to the proportion of optimal actions for 250 students across 1000 trials, treating the number of contextual variables as a covariate.

Baseline: When student features do not influence outcomes, we see that as expected, the non-contextual bandit outperforms the contextual bandit (Table 2): average performance per student for the final 50 out of 1000 students using the contextual algorithm is similar to that of the first 250 students using the non-contextual algorithm (Figure 2). As the number of student features increases, the contextual MAB chooses a lower proportion of optimal actions for the first 250 students (Figure 1a), but the effect is relatively small especially when considering the impact on actual reward ($t(13996) = -10.880$, $p < 0.001$, $b = -0.006$, 95% CI = $[-0.007, -0.005]$). At longer horizons, the number of student features has less of an impact on overall average reward (Figure 2), which we discuss more below.

Universal optimal action: When outcomes are dependent on student features, the contextual MAB algorithm can learn a more accurate model than the non-contextual algorithm. However, when this more accurate model is not needed for optimal action choices, learning the more accurate model does not improve action choices: the non-contextual bandit outperforms the contextual bandits in all four scenarios (Table 2; see Figure 1b for scenario 1). While each scenario might arise due to different educational conditions, they are all very similar in how they appear to the non-contextual bandit algorithm. The non-contextual bandit sees the two groups of students as identical, leading the overall performance to be the average for each group. These changes in the average effectiveness of each intervention impact the algorithm's performance but do not necessarily degrade that performance; instead, the impact is dependent

²In pilot simulations, this encoding led to better performance than if only a single coefficient was learned for each feature, and corrected asymmetries in performance for students who had different values of the feature.

Figure 1: Swarm plots for the proportion of optimal actions for the two bandit types. Each point represents results from one trial with 250 students. For the universal optimal action, all scenarios show similar results; hence only scenario (1) is shown. The bimodality of the contextual bandits, especially at low numbers of contextual variables, highlights the potential risks of personalization.

	Superior bandit	$ b $	95% CI	$F(1, 13996)$	p	Cohen's d
Baseline	Non Contextual	0.098	[0.089, 0.108]	2678.0	< .001	0.871
Universal optimal action (1)	Non Contextual	0.088	[0.079, 0.097]	2750.0	< .001	0.880
Universal optimal action (2)	Non Contextual	0.078	[0.072, 0.085]	3853.0	< .001	1.042
Universal optimal action (3)	Non Contextual	0.101	[0.092, 0.11]	2891.0	< .001	0.904
Universal optimal action (4)	Non Contextual	0.074	[0.063, 0.085]	1865.0	< .001	0.725
Personalized optimal action	Contextual	0.295	[0.287, 0.302]	10816.0	< .001	1.677

Table 2: Inferential statistics for proportion of optimal actions for the two bandit types across all outcome-generating models, simulated for 1000 trials of 250 students each. b represents the coefficient of improvement of results for the superior bandit after controlling for the number of contextual variables.

Figure 2: Average reward per student across 1–10 contextual variables for the two bandit types in the baseline model. In this model, the maximum expected reward is 0.6, and the expected reward for uniform random assignment is 0.5. Error bars represent 1 standard error.

on how similar the two interventions are in their expected outcomes and how close those expected outcomes are to 0.5, where there is the most variance.

Personalized optimal action: When the best policy for individual students depends on their features, the contextual bandit significantly outperforms the non-contextual bandit (Table 2). When only one student feature is included, the contextual MAB algorithm chooses the optimal action almost 70% of the time for the first 50 students; this increases to almost 90% for the final 50 of the total 250. Including extra student features decreases performance - if ten features are included and only one impacts the policy, the overall

proportion of optimal actions falls to about 65%. Yet, this is still an improvement over the non-contextual algorithm (Figure 1c). These results suggest that even if a relatively small number of students will interact with the system and one is uncertain about which of a (limited) set of features will impact results, including those features will on average have a positive impact on student outcomes if one is confident that the best version of the system for an individual student varies based on one of those features.

Variability across simulations: Examining variability across simulations provides insight into how likely actual deployments of these algorithms are to reflect their average performance. Across all models, the contextual MAB algorithm exhibited greater variability in performance than the non-contextual MAB algorithm (Figure 1). Surprisingly, increasing the number of student features leads to lower variance for the contextual MAB algorithm. With small numbers of student features, there is often a concentration of simulations with lower achieved outcomes, resulting in bimodal distributions (Figure 1). The bimodality emerges because the algorithm can adapt more quickly, making it somewhat more vulnerable to underestimating parameter values based on a few samples with unexpected low rewards. Because the parameter estimates influence future action choices, data to correct these underestimates may not be collected quickly enough (as has been documented for non-contextual bandits in, e.g., [10]). In contrast, increasing the number of student features increases variation near the mean but eliminates the bimodality (Figure 1) since the algorithm performs more exploration to learn the larger number of parameters.

This makes it less likely to collect data that lead to erroneous conclusions about the effectiveness of actions. Errors in the parameter values are more likely to be corrected because they are unlikely to lead to the same choices for all student features, hence creating more variability in action choice for students with a specific value of a single feature. Indeed, the simulation results support these interpretations: for the baseline and universal optimal action models in a 1000-student classroom (see Figure 2 for baseline), average reward for the first 250 students is lower but reward for the final 50 students is higher as the number of contextual variables increases. There is thus a trade-off between expected outcomes and variability: the ability of the contextual MAB algorithm to adapt more quickly when it has fewer features to learn comes at the cost of it being less able to correct for wrong conclusions from small amounts of data.

Variability in policies across students: As noted above, the extra parameters learned by the contextual MAB algorithm lead to the potential for greater variability in action choices within a single simulation. This can systematically affect groups of students when the algorithm attaches spurious relevance to a feature that does not actually impact outcomes. We can see this pattern by examining differences in action probabilities for students who differ only by characteristics that do not impact outcomes: that is, considering all students who have the same value for the first feature, how does the probability of choosing a particular action change based on their different values for the other features? As the number of contextual variables increases, the average maximum difference in action choice probability between such students also increases from 18–25% when two student features are included in the model to over 90% when ten features are included in the model after running through 250 students. This occurs both based on the greater expressivity of the model with more student features and the fact that the model with more student features is likely still learning about the impact of each of these features. This raises potential concerns about inequity: students who should be treated identically by the system may instead be treated systematically differently, based on features that do not impact how they learn.

5. IMPACT OF UNEVEN DISTRIBUTION OF STUDENT CHARACTERISTICS

The results of the previous simulations demonstrate that in situations where student characteristics (features) impact the outcome of different educational interventions, a contextual MAB algorithm only provides an improvement over a non-contextual algorithm when knowledge about the characteristic is necessary for choosing the best action. These simulations provided insight into how performance is impacted by different patterns of relationships between student characteristics and outcomes, with the assumption that those characteristics were uniformly distributed. However, in reality, some characteristics are likely to be more common than others. For example, when optimizing which hint to give to students who answer a question incorrectly, the algorithm is more likely to encounter a student with lower prior knowledge than one with higher prior knowledge. Thus we now relax this assumption and explore how changing the distribution of student characteristics impacts student outcomes for both types of MAB algorithms. In these simulations, we

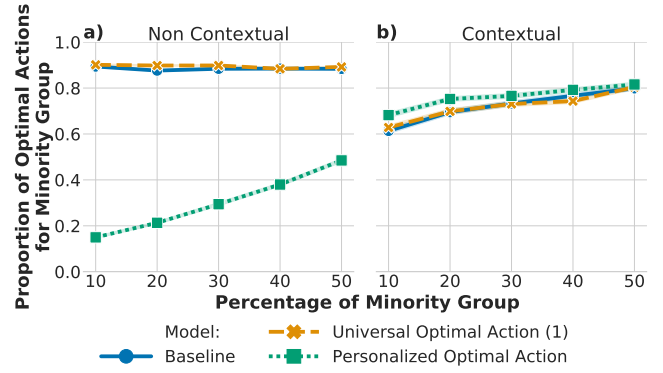

Figure 3: Proportion of optimal actions for minority groups with sizes of 10%–50% for the two bandit types across the three outcome-generating models, limited to one contextual variable. Standard errors, represented by the translucent bands, are negligible.

examined not only overall outcomes, but also outcomes for different groups of students. Attention to group-specific outcomes is vital for identifying inequitable impacts of adaptive algorithms.

5.1 Methods

Similar to the first set of simulations, we compared non-contextual and contextual MAB implementations that used Thompson sampling across the same three horizons of 50, 250, and 1000 students, with a focus on 250; we repeated each simulation 1000 times. These simulations include a new independent variable: the proportion of students in each group. Specifically, for each simulated student, we varied the probability of the student being in the minority group (i.e., having a value of one for the first student characteristic) from 10% to 50%, using 10% increments. In addition to analyzing performance across all students, we examined performance for both the minority and majority groups separately. We also examined the *balanced success rate*, defined as the simple average of the group-specific performances [5]. Balanced success rate provides a way of examining performance that treats each group as equally important, even though one group may have more students than another.

5.2 Results

As in the previous analysis, we used an ANCOVA to compare the performance for the two bandit types in terms of the proportion of optimal actions, but this time treating the percentage of the minority group as a covariate.

One student characteristic: With one student characteristic, the contextual MAB algorithm’s performance for the minority group decreases as the size of the minority group becomes smaller, across all outcome-generating models (Figure 3b and Figure 4; $t(59996) = -33.962$, $p < 0.001$, $b = -0.427$, 95% CI = $[-0.452, -0.402]$). This leads the contextual MAB algorithm to have a lower balanced success rate for smaller minority groups. However, overall performance across all students is slightly better since so many more students are in the majority group (Figure 4; $t(59996) = 16.633$, $p < 0.001$, $b = 0.126$, 95% CI = $[0.111, 0.141]$). In other

Figure 4: Comparing the proportion of optimal actions of the contextual bandit between 1 and 5 student features (i.e., contextual variables) for the majority and minority groups, as well as their balanced and overall averages, across minority group sizes of 10%–50%. Standard errors, represented by the translucent bands, are negligible.

words, decreasing the minority group size hurts the minority group more than it helps the majority group on a per-student basis; but replacing students from the minority group, who are assigned worse conditions, with students from the majority group, who are assigned better conditions, increases overall reward.

This pattern of results occurs because the contextual MAB has more uncertainty about the impact of the particular value of the student characteristic that appeared fewer times: in the least balanced case, we expect the minority group to be seen only 25 times on average given a horizon of 250 students. Hence, providing a model with the potential to personalize for a minority group is a calculated risk - although the extra expressivity is likely intended to improve experiences for all groups of students, it can negatively impact minority groups, with a larger negative impact for smaller minority groups.

In contrast, the non-contextual MAB algorithm is relatively unaffected by the changing distribution of student characteristics in both the baseline ($t(9996) = 0.497$, $p = 0.619$) and universal optimal action scenarios ($t(39996) = 1.506$, $p = 0.132$), as shown by Figure 3a. The changing distribution of student characteristics changes the expected rate of obtained reward from each action, but the changes are small enough that they have little impact on the algorithm’s ability to choose optimal actions.

However, for the personalized optimal action model, the size of the minority group *does* have a large impact on individual student outcomes for the non-contextual MAB algorithm: when the minority group is small, the algorithm learns to choose the action that is best for the majority and worst for the minority, resulting in the optimal action being chosen only 15% of the time for the minority group, within a horizon of 250 students (Figure 3a). When the two groups are of equal size, the algorithm has no systematic information that shows one action as consistently better or worse than the other; thus on average, it chooses the optimal action about 50% of the time for both groups.

Additional student characteristics for the contextual MAB algorithm: When the number of student characteristics increases, the impact on the minority and majority groups differs for the baseline and universal optimal action models compared to the personalized optimal action (Figure 4). In the two former models, the impact on balanced success rate is generally small: as the number of student characteristics increases from one to five, balanced success decreases no more than 8%, except by 11% in universal optimal action (4); for most of these models, the decrease is even smaller when the minority group is smaller. In these models, the algorithm’s performance for small minority groups is improved with more student characteristics, while performance for majority groups decreases. For example, in the baseline scenario with 10% of students in the minority group, the algorithm chooses the optimal action for 71% of the minority group when there are five student characteristics, compared to 61% of these students when there is only one student characteristic. More student characteristics leads to more exploration with the initial students, and thus the algorithm is less likely to systematically execute a bad policy for the minority group based on a small number of initial samples.

For the personalized optimal action scenario, increasing the number of student characteristics from one to five decreases performance for both minority and majority groups by about 15% regardless of the size of the minority group, uniformly lowering balanced success rate. Due to the extra exploration caused by the extraneous student characteristics, the algorithm is slower to exploit the actual relationship between the relevant student characteristic and the action choice, without differential impact based on minority group size.

6. REAL-WORLD EXPERIMENTS

The first two sets of simulations can guide system designers when making decisions about personalizing based on student features. However, they have some limitations: while they considered a relatively large space of possibilities for how outcomes relate to student features, they focused on showing a general variety of cases rather than on specific cases that might be most common or of particular interest

	Problem Set	Students	Q1 Size	Q2 Size	Q3 Size	Q4 Size
Uneven Student Distribution	293151	320	113 (35.3%)	100 (31.3%)	69 (21.6%)	38 (11.9%)
Even Student Distribution	263057	129	33 (25.6%)	28 (21.7%)	34 (26.4%)	34 (26.4%)

Table 3: Student totals and group distributions in the original ASSISTments data [23] for the two problem sets of interest. Prior percent correct is discretized before removing students who have never answered incorrectly to experience the assigned condition, biasing group size towards the lower quartiles in the Uneven Student Distribution.

Figure 5: Original average reward per student in the ASSISTments data [23], across the four quartiles (Q1–Q4) of prior percent correct and their averages, for the two conditions in the experiments (control and experimental) illustrates our model parameters of real-world scenarios.

in education. To address this, we conducted several case studies of how MAB algorithms would have impacted actual experiments. We consider existing experimental data in which the optimal action would be personalized to see if the contextual MAB algorithms benefits students (as would be expected from our previous simulations) and also to demonstrate how factors from the previous simulations manifest in real-world scenarios.

The experiments were previously conducted within *ASSISTments*, an online learning system, and focused primarily on middle school math. We selected several experiments from [23] based on how student outcomes were related to their prior successes in the system as well as their assignment of either the control or experimental condition. Prior success in the system is a strong candidate to be a student feature for personalization: it is typically easily available and can serve as a proxy for prior knowledge, which has been shown to influence the success of different instructional strategies [25].

6.1 Methods

To model previously collected ASSISTments data in our MAB framework, we (1) transformed both the student characteristics and the student outcomes into discrete variables,³ and (2) resampled from the data to generate outcomes when the MAB algorithm assigned a condition.

For step (1), we first discretized students’ prior percent correct on problems within ASSISTments, the sole student feature that we included for personalization, into four quartiles: the 25% of students who began the homework assignment with the lowest prior percent correct (Q1), then those in the 26–50% range (Q2), and so on. The dataset contains some students who began the homework but were not assigned to

³MAB algorithms can handle non-categorical data, but we focus on the categorical case to mirror our prior simulations.

a condition. Since the experiments in [23] mainly manipulated students’ experiences (e.g. type of hint) when they answered a question incorrectly, students who have never answered incorrectly are not included in the experiment results (nor will the MAB algorithm make choices for them). However, they are included in the quartile cutoffs, which means that in the population of students with whom the MAB algorithm interacts, the number of students in each quartile may not be uniform.

We also chose and discretized the student outcome measures. These experiments included two different measures of student outcomes: whether each student completed the homework and the number of problems that each student answered in the homework. All experiments took place in the *SkillBuilder* interface, where students must answer three consecutive problems correctly to complete the homework. Completion of homework (denoted *Completed HW*) is already discrete and could easily be collected in real time; two of our simulations use this measure. However, it is relatively coarse, as the vast majority of students completed the homework. Thus, we also used a discretized version of the number of problems to completion (denoted *Completed Quickly*). If a student completes the homework, doing so in fewer problems is a better outcome than doing so in more problems. Outcomes were based on the median problem count for students who completed the homework. Students who completed the homework in the median number of problems or fewer had positive reward, while those who did not complete the homework or completed it more slowly had no reward. Though for practical use prior data would be needed to select an appropriate cut point, using a cut point based on collected data in our simulations measures the performance of students more closely.

For step (2), we simulate a MAB algorithm’s performance by repeatedly sampling students from the experiment. Within each trial, we fix the number of timesteps to the total num-

Figure 6: Swarm plots for the proportion of optimal actions for the two bandit types for each quartile of prior percent correct and their averages. Each point represents results from each of the 1000 trials per experiment and the solid black lines indicate the means of each swarm plots. Points for Q4 of Even Student Distribution, Completed HW are clustered at 1.0 because both actions are optimal. The extra information learned by the contextual bandit improves performance in most cases but the bimodality for some quartiles demonstrates the associated systematic risks.

ber of students in the original experiment. At each timestep, a random student is sampled, and the algorithm then selects a condition for that student. To compute the outcome, we sample from all outcomes for students in the experiment who were in the same quartile for prior percent correct and who experienced the same chosen condition. Each trial thus represents an experiment of the same size as the original, with the students drawn with replacement from the experimental data. We randomized each of the 1000 trials, though for each trial, we use the same student ordering for both types of MAB algorithms.

In our case studies, we focus on one problem set (#293151) where students are unevenly distributed across quartiles, with more lower-performing students (Q1), and one problem set (#263057) in which students are more evenly distributed across quartiles (see Table 6). With the two different outcome measures, this resulted in four simulation scenarios. We chose these problem sets because they had student outcomes that varied based on both condition and student quartile (see Figure 5).

6.2 Results

In all four settings, at least one quartile of students (out of Q1–Q4) was helped by the contextual MAB algorithm, and in three of the four settings, average outcomes across all students were improved by personalization.

Uneven Student Distribution, Completed HW: As shown in Figure 6a, in this scenario, students in Q4 were much more likely to experience their optimal condition with a contextual MAB algorithm. This occurs because the condition that is best for the average student is the one that is worse for Q4: the non-contextual MAB thus optimizes in a way that has a systematic, negative outcome for Q4 students. Conversely, the contextual MAB algorithm does not do as well as the non-contextual algorithm for students in Q1–Q3 because of the extra exploration needed to learn about more variables that are not necessary to help these students. Overall, this means that the contextual MAB algorithm had a slightly lower rate of choosing the optimal action than the non-contextual MAB. However, the difference is relatively small, and is even smaller in terms of average

reward: reward is reduced by less than 0.01 overall, while is increased for Q4 students by about 0.06. In this experiment, reward rates are high in general (greater than 70% for all conditions and quartiles). Thus with 320 students, small differences in condition assignment often are not reflected in large differences in outcomes. Q1–Q3 students have very similar outcomes across the two methods of condition assignment; Q4 has the greatest difference in success for one condition versus another, and thus the large increase in optimal condition assignment for these students does boost the average outcomes.

Uneven Student Distribution, Completed Quickly:

Using the Completed Quickly outcome measure with the same students, students in all quartiles were more likely to be assigned to the optimal condition when the contextual MAB algorithm was used (Figure 6b). This pattern occurs because the overall probability of a positive outcome is very similar across the two conditions when student quartiles are ignored (shown by *All* in Figure 5b), making it difficult for the non-contextual bandit to learn that the experimental condition is better on average. In contrast, the differences between conditions are large for all quartiles except Q2. Thus, the information from the student quartiles makes the problem easier for the contextual MAB algorithm, though the relatively small difference between conditions for Q2 results in the lowest overall proportion of optimal action choices. This simulation thus importantly shows a scenario that was not explored in the prior simulations, in which knowing about extra information increases the number of parameters to learn but makes learning about each of those individual parameters easier.

Even Student Distribution, Completed HW: For this scenario, there were again very high reward probabilities across all conditions, and a relatively small overall difference between conditions but larger differences between conditions for three of the four quartiles. The results from the previous simulation were mirrored here: all groups with some reward rates of less than 100% were aided by the contextual MAB algorithm.

Even Student Distribution, Completed Quickly: Finally, using the Completed Quickly outcome measure for this

second set of students, the results were still largely in favor of the contextual MAB algorithm. As the experimental condition is better on average, students in Q1 experience a large positive impact through personalization because the control condition is uniquely better for them. Q2 and Q3 also experience positive impacts, with the impact on Q2 students being larger because the difference between the two conditions is larger, which speeds learning for the contextual bandit. Conversely, Q4 students experience slightly less positive outcomes under the contextual MAB algorithm because the small difference between conditions slows learning; in comparison, the contextual MAB algorithm is more beneficial for Q4 students since the overall difference between conditions across all students is larger than the difference for Q4 students only.

Variability in real-world scenarios: Variability across trials in these scenarios showed the same trend as in the previous simulations: the non-contextual MAB algorithm typically has slightly more variation around the mean of the distribution, but only the contextual MAB algorithm shows bimodality, with some trials showing very poor performance for at least one of the groups (Figure 6).

7. DISCUSSION

Real-time adaptive algorithms can respond quickly to optimize experiences for individual students, and their expressivity for personalizing experiences increases with each additional type of student information they are given. In this paper, we have shown that this expressivity is worthwhile only when it is *necessary* for expressing the best policy to improve student outcomes. It is also especially helpful in cases where student characteristics are not uniformly distributed. In that case, an algorithm without the extra information may instead learn a policy that systematically optimizes for the majority but not for a minority group. However, when this expressivity is not necessary, it increases variability across students and also increases the time for identifying the correct policy, thus significantly decreasing the number of students assigned the best version of the technology and slightly decreasing their average outcomes. Despite this, the results based on the real-world experimental data clarify the potential benefits of personalization by demonstrating that having extra information about students can sometimes make learning easier, outweighing the negative impact of learning additional parameters.

There are several limitations to our results. First, we have focused only on discrete student features and discrete outcomes but continuous parameters are also common. For example, we might measure student scores rather than homework completion or model prior knowledge as an estimated ability parameter. If one wanted to extend these analyses to real-valued student features, one could easily incorporate them into the current modeling framework with versions of Thompson sampling for real-valued outcomes [2], and there exist metrics from a large literature for assessing whether students are treated fairly (e.g., [6]). Using real-valued parameters is unlikely to significantly impact trends in results, except that defining student groups for analyzing equitable outcomes is more difficult. Our results from our universal optimal action scenarios show that, with binary rewards, knowledge of the student features is not beneficial if it is

unnecessary for expressing the best policy. However, these results may not translate to the real-valued rewards case, where the latent student features will add to the variability in the distributions observed by the non-contextual bandit, and exploring these scenarios is an important step for future work. A second limitation is that our simulations comprise only a single student feature that influences the outcome, though in actual deployments multiple features may influence the best policy. Still, we believe that our results can guide system designers when thinking about such scenarios, especially in weighing the costs and benefits of including each possible variable.

The results from the real-world scenarios highlight the potential value of MAB algorithms for educational technologies. For almost all scenarios and groups, both types of MAB algorithms chose the optimal condition more often than if students had been assigned uniformly at random, and average rewards were in many cases very close to the optimal expected reward (i.e. if the optimal action had been chosen for all students). The absolute difference in rewards was relatively small between the two bandit types—at most 0.075—and the contextual bandit achieved at worst 12% less than the optimal expected reward for any student group. Yet the earlier simulations urge caution for incorporating student characteristics, due to (1) decreases in achieved outcomes when these characteristics are unnecessary, (2) increases in variability of performance, and (3) the systematically different treatment of students based on irrelevant characteristics. Thus, system designers should weigh the risk of not personalizing when the best policy for the minority differs from the majority with these side effects of personalization and ultimately strive to only include variables that past evidence suggests differentially impact outcomes.

One could make a number of extensions of this work for using MAB algorithms to improve and personalize educational technologies. First, contextual MAB algorithms might mitigate issues of biases when different types of students interact with an educational technology and while all are most helped by the same version of the technology, their outcomes have different distributions. For example, struggling students may complete homework later, leading the MAB algorithm’s early estimates to be non-representative of the broader population. Prior work has shown that this bias significantly worsens inference about the effectiveness of the technology as well as expected student outcomes [20]: the use of a contextual MAB algorithm could allow the system to adapt to such differences across students. Second, if the technology is used by a large number of students, the set of variables used by the contextual algorithm could be increased as more data are collected. Such a system might improve consistency across student outcomes, while still personalizing based on truly relevant features that are justified the sufficient information collected. The work in this paper both provides a starting point for considering what scenarios, algorithms, and metrics should be explored in future work, as well as guidance for system designers who would like to deploy MAB algorithms within their own technologies but are uncertain about which student characteristics, if any, to include for personalization.

ABSTRACT

Modeling student learning processes is highly complex since it is influenced by many factors such as motivation and learning habits. The high volume of features and tools provided by computer-based learning environments confounds the task of tracking student knowledge even further. Deep Learning models such as Long-Short Term Memory (LSTMs) and classic Markovian models such as Bayesian Knowledge Tracing (BKT) have been successfully applied for student modeling. However, much of this prior work is designed to handle sequences of events with *discrete timesteps*, rather than considering the continuous aspect of time. Given that time elapsed between successive elements in a student's trajectory can vary from seconds to days, we applied a Time-aware LSTM (T-LSTM) to model the dynamics of student knowledge state *in continuous time*. We investigate the effectiveness of T-LSTM on two domains with very different characteristics. One involves an open-ended programming environment where students can *self-pace* their progress and T-LSTM is compared against LSTM, Recent Temporal Pattern Mining, and the classic Logistic Regression (LR) on the early prediction of student success; the other involves a classic *tutor-driven* intelligent tutoring system where the tutor scaffolds the student learning step by step and T-LSTM is compared with LSTM, LR, and BKT on the early prediction of student learning gains. Our results show that T-LSTM significantly outperforms the other methods on the self-paced, open-ended programming environment; while on the tutor-driven ITS, it ties with LSTM and outperforms both LR and BKT. In other words, while time-irregularity exists in both datasets, T-LSTM works significantly better than other student models when the pace is driven by students. On the other hand, when such irregularity results from the tutor, T-LSTM was not superior to other models but its performance was not hurt either.

1. INTRODUCTION

Student Modeling sits at the epicenter of educational data mining. It monitors a student's progress, ability, or knowledge over a set of skills and can predict the student's future performance based on historical sequence data. In recent years, recurrent neural network architectures, such as Long Short-Term Memory (LSTMs), have become the workhorses for modeling sequence data in a variety of tasks involving sequential data, such as video processing, climate change detection, and patient disease progression prediction [20, 19, 25, 12]. Deep Knowledge Tracing [35, DKT], the first LSTM approach in student modeling, reported an impressive improvement over a classical statistical model Bayesian Knowledge Tracing [10, BKT]. Both LSTM/DKT and BKT are designed to handle sequences of events with *discrete timesteps*, not considering the *continuous* aspect of time.

On the other hand, student response time, the elapsed times between consecutive elements of a sequence can vary greatly by student, from seconds to days. Ever since the mid-1950s, student response time has been used as a preferred educational assessment to evaluate how active and accessible student knowledge is in cognitive psychology [43]. For example, it has been shown that response time reveals student proficiency [40] and there is a significant negative correlation between student average response time and student final exam score taken at the end of the semester [16]. Additionally, response time has been suggested as an indicator of student engagement in answering questions [21] as well as an important factor for predicting motivation in learning environments [9]. Also, by leveraging time information, BKT prediction performance can be improved [38, 44]. Therefore, by not taking the time intervals into consideration, the design of traditional LSTM and BKT may lead to sub-optimal performance for modeling student learning.

Previous work for modeling sequence data has explored several ways to handle time irregularity [3, 34, 8, 6] and among them, Time-aware LSTM (T-LSTM) is one of the most state-of-the-art models [3]. T-LSTM transforms time intervals between successive elements into weights and uses them to adjust the memory passed from previous moments. In this work, we apply T-LSTM to model the dynamics of student knowledge state *in continuous time* and conduct two empirical comparisons between T-LSTM and the standard LSTM, Recent Pattern Mining [23], and classical student model-

Ye Mao, Samiha Marwan, Thomas Price, Tiffany Barnes and Min Chi "What Time is It? Student Modeling Needs to Know" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 171 - 182

ing methods such as BKT and logistic regression models on two real-world data sets collected from two learning environments with very different characteristics. One is an open-ended block-based programming environment for a novice programming task where students are free to explore the environment with minimal system support or constraints. Each student's log file is a trajectory of actions with corresponding time stamps and time intervals calculated between the two consecutive student actions. The other probability tutor is *tutor-driven* in that *the tutor* decides what to do next. Each student's log file is a trajectory of student-ITS interactions. In each interaction, the tutor first *elicits* the subsequent step from a student with prompting, and when the student performs a step, the tutor records its success or failure and may give feedback (e.g. correct/incorrect markings); if the student's answer is incorrect, the tutor provides a series of hints from general to specific and the bottom-out hint tells the student exactly what to do. The interaction is ended only when a step is correctly answered and the tutor moves to the next interaction. As a result, each student's log file is a trajectory of tutor actions mixed with student's responses with corresponding time stamps. In this environment, the time intervals are calculated between the student's *first attempt* on one problem and the next. Our research question is: *By taking time-awareness into consideration, would T-LSTM outperform other traditional student modeling methods on both self-paced and tutor-driven learning environments?*

2. METHODS

2.1 Long Short-Term Memory

Long Short Term Memory [18, LSTM] is a special type of RNN which is explicitly designed to avoid the long-term dependency problem. LSTM can avoid the vanishing (and exploding) gradient problem and works tremendously well on a large variety of problems.

Figure 1: The Structure of a LSTM Unit

The internal structure of each LSTM module is shown in Figure 1. There are three major components: a forget gate, an input gate, and an output gate in a standard LSTM unit cell, where these components interact with each other to control how information flows. In the first step, a function of the previous hidden state h_{t-1} and the new input x_t passes through the forget gate, indicating what is probably irrelevant and can be taken out of the cell state. The for-

get component will calculate a weight f_t between 0 to 1 for each element in hidden state vector C_{t-1} . An element with a weight of 0 should be completely forgotten whereas an element with a weight of 1 needs to be entirely remembered. The formula to calculate f_t is shown below where W_f and b_f are the weights and intercepts, respectively, for the forget component.

$$f_t = \text{sigmoid}(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (1)$$

There are two steps involved in input component's calculation. In the first step, a *tanh* layer calculates a candidate vector \tilde{C}_t that could be added to the current hidden state. In the second step, the input components calculate a weight vector i_t (ranging from 0 to 1) to determine to what extent \tilde{C}_t should update the current memory state.

$$\tilde{C}_t = \tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \quad (2)$$

$$i_t = \text{sigmoid}(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (3)$$

With the forget and input components, the module is able to throw away the expired information in the previous cell state by calculating $C_{t-1} \cdot f_t$, and process new information by computing $\tilde{C}_t \cdot i_t$. Consequently, the formula to update the current memory cell is shown below. Note that the current memory cell state C_t is then passed to the next LSTM module.

$$C_t = C_{t-1} \cdot f_t + \tilde{C}_t \cdot i_t \quad (4)$$

Finally, the output component is simply an activation function that filters elements in C_t . The C_t can be converted to a value between -1 to 1 by the tanh function. The output component calculates a weight vector

$$o_t = \text{sigmoid}(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (5)$$

that determines how much information is allowed to be revealed.

$$C_t = o_t * \tanh(C_t) \quad (6)$$

With such a gated structure, LSTM is capable of handling long-term dependencies.

2.2 Time-Aware Long Short Term Memory

The standard LSTM assumes that the elapsed times between elements of a sequence are uniformly distributed, and therefore it is designed to handle sequences with *discrete timesteps*. However, in the educational domain, the interval between two consecutive steps during a student trajectory can span from seconds to days. In general, the events that occurred long ago tend to have less impact to the current state and thus we should properly reduce their contributions. Therefore, it is important to consider the elapsed time when predicting the current event's output. In this work, we applied Time-aware LSTM [3, T-LSTM], which is proposed to handle the temporal dynamics of sequential data with time irregularities, to model student knowledge states *in continuous time*.

The T-LSTM architecture is shown in Figure 2. To fit in our domain, we represent the input sequence by the student trajectories. Apart from the three gates in standard LSTM: forget, input, and output; T-LSTM also integrates the time elapsed between successive records into the network architecture, and we call this as the time decay component. The information stored in the memory of the previous

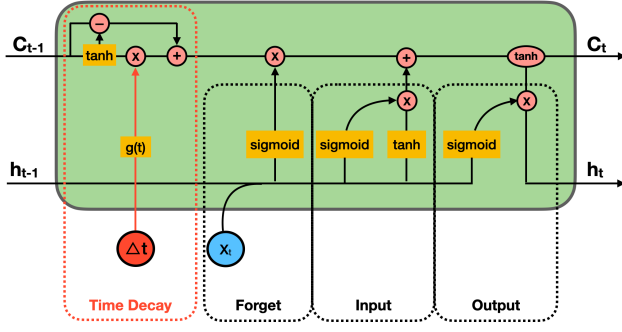

Figure 2: The Structure of a T-LSTM Unit

hidden state C_{t-1} is decomposed into two parts: long-term memory and short-term memory. Without losing the long-term memory contained in C_{t-1} , the time decay component mainly plays a role to adjust the short-term memory by employing the elapsed time between successive steps. If the gap between two steps is significantly huge, e.g. few hours in our domain, it means there has been a long time with no interaction between students and the tutor/computer. In that case, there is not much point to heavily rely on the previous short-term memory to predict the current output. In the framework of T-LSTM, a non-increasing function of the elapsed time is applied to transform the time duration into an appropriate weight. And in this work, we applied $g(\Delta t) = 1/\log(e + \Delta t)$ to get the corresponding weights.

The following calculations are involved in the time decay component of T-LSTM. First, short-term memory C_{t-1}^S is calculated.

$$C_{t-1}^S = \tanh(W_d \cdot C_{t-1} + b_d) \quad (7)$$

The long-term memory can be obtained by deducting short-term memory from the previous hidden state.

$$C_{t-1}^L = C_{t-1} - C_{t-1}^S \quad (8)$$

Then C_{t-1}^S is discounted by the elapsed time weight to obtain the discounted short-term memory \hat{C}_{t-1}^S .

$$\hat{C}_{t-1}^S = C_{t-1}^S * g(\Delta t) \quad (9)$$

Finally, the adjusted previous hidden state C_{t-1}^* is composed by adding long-term memory and discounted short-term memory.

$$C_{t-1}^* = C_{t-1}^L + \hat{C}_{t-1}^S \quad (10)$$

The following parts are very similar to standard LSTM. Following the steps in Section 2.1, we first calculate the forget gate f_t , candidate vector \tilde{C}_t and input gate i_t by applying Equation (1), (2) and (3). For the calculation of the current memory cell state C_t , the adjusted previous hidden state C_{t-1}^* instead of C_{t-1} is applied in the T-LSTM framework.

$$C_t = C_{t-1}^* \cdot f_t + \tilde{C}_t \cdot i_t \quad (11)$$

The final output for the current state can be achieved using the following Equation (6). In this work, we investigate the effectiveness of T-LSTM via the early prediction of both student success and learning gains. As far as we know, no prior studies have explored T-LSTM on both computer-based programming systems and intelligent tutoring systems.

2.3 Recent Temporal Pattern Mining

The Recent Temporal Pattern mining (RTP) framework [2] was originally proposed to find predictive patterns from complex multivariate time series data. This framework first converts time series into time-interval sequences of temporal abstractions, and then constructs more complex temporal patterns backwards. The following part will explain how the RTP framework is applied in our work.

Multivariate State Sequences: We denote a **State** S as (F, V) , where F is a temporal feature and V is the value for feature F at a given time and the **State Interval** E is denoted as (F, V, s, e) , where s and e refer to the *start* and *end* times of the state (F, V) . Thus, we can convert each student's data x_i into a corresponding Multivariate State Sequence (MSS) z_i by sorting all the state intervals by their start times: $z_i = \langle E_1, E_2, \dots, E_n \rangle : E_j.s \leq E_{j+1}.s, j \in \{1, \dots, n-1\}$. And we apply two temporal relations in this work: 1) E_i **before(b)** E_j : When E_i ends before the start of E_j ($E_i.e < E_j.s$); 2) E_i **co-occurs(c)** with E_j : When E_i and E_j have some overlap ($E_i.s \leq E_j.s \leq E_i.e$).

Recent Temporal Patterns: Here, we call a state interval $E = (F, V, s, e)$ a *Recent State Interval* of MSS z_i if: 1) E is the last state interval for feature F ; that is, for all $E' = (F, V', s', e')$, we have $E'.e \leq E.e$; or 2) E is less than g time units away from the end time of the last state interval: $z_i.end$; that is, $z_i.end - E.e \leq g$.

Given an MSS z_i , a temporal pattern $P = (\langle S_1, \dots, S_n \rangle, R)$, and a maximum gap parameter g , we say P is a recent temporal pattern (RTP) in z_i , denoted $R_g(P, z_i)$, if all 3 of the following conditions hold: 1) z_i contains P , where $P \in z_i$ if: (a) z_i contains all k states of P , and (b) all temporal relations of P are satisfied in z_i ; 2) $S_n = (F_n, V_n)$ matches a recent state interval in z_i ; and 3) Every consecutive pair of states in P maps to a state interval less than g time units apart. That is, each pair of temporal sequences should not be g time units apart. In short, parameter g forces patterns to be close to the end of the sequence z_i , and forces consecutive states to be close to each other.

Mining Algorithm: Taking student success classification as an example, we will have two sets of labeled MSSs: $Z_1 = \{z_i : y_i = 1\}$ for all *unsuccessful* sequences and $Z_0 = \{z_j : y_j = 0\}$ for all *successful* ones. Given Z_1 , the mining algorithm applies a level-wise search to find frequent RTPs. More specifically, it first starts with all frequent 1-RTPs, and then extends the patterns by adding a new state to each sequence, one at a time, until no new patterns are discovered. That is, at each level k , the algorithm finds frequent $(k+1)$ -RTPs by repeatedly extending k -RTPs through Backward candidate generation, and the Counting phase, as described below.

Backward $(k+1)$ -pattern candidates are generated from a k -pattern $P = (\langle S_1, \dots, S_k \rangle, R)$, by adding a new frequent state, S_{new} , to the beginning of the sequence to create $P' = (\langle S_{new}, S_1, \dots, S_k \rangle, R')$. Then we specify the new before (b) or co-occurs (c) relations R' between S_{new} and all original k states, restricted by the following two criteria: 1) Two state intervals of the same temporal feature cannot co-occur.

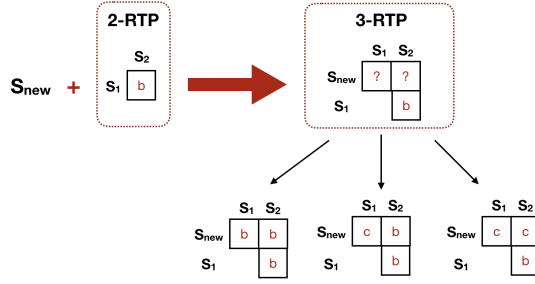

Figure 3: An example of generating 3-patterns out of a single 2-RTP, by appending a new state.

That is, if $S_{new} \cdot F = S_i \cdot F$ for $i \in \{1, \dots, k\}$, then $R'_{new,i} \neq c$. 2) Since the state sequence in pattern P is sorted by the start time of the states, once a relation becomes *before*: $R'_{new,i} = b$ for any $i \in \{1, \dots, k\}$, all of the following relations have to be *before*, so $R'_{new,j} = b$ for $j \in \{i + 1, \dots, k\}$.

In the Counting phase, candidate $(k + 1)$ -patterns are removed if they do not meet the minimum support threshold by occurring at least σ times as RTPs in Z_1 . The same procedure is carried out for Z_0 . Finally, we combine all the frequent RTPs into a final Ω set of RTPs.

Binary Matrix Transformation: We transform each MSS $z_i \in Z$ into a binary vector v_i of size $|\Omega|$, such that each 0 and 1 indicates whether the pattern $P_j \in \Omega$ is a recent temporal pattern in Z_i or not. This will result in a binary matrix of size $N \times |\Omega|$, which represents our original dataset.

2.4 Bayesian Knowledge Tracing

BKT is a student modeling method extensively used in ITSs. Figure 4 shows a graphical representation of the model and a possible sequence of student observations. The shaded nodes S represent hidden knowledge states. The unshaded nodes O represent observation of students' behaviors. The edges between the nodes represent their conditional dependence.

Figure 4: The Bayesian network topology of the standard Knowledge Tracing model

Fundamentally, the BKT model is a two-state Hidden Markov Model [11, HMM] characterized by five basic elements: 1) N , the number of different types of hidden state; 2) M , the number of different types of observation; 3) Π , the initial state distribution $P(S_0)$; 4) T , the state transition probability $P(S_{t+1}|S_t)$ and 5) E , the emission probability $P(O_t|S_t)$. Note that both N and M are predefined before training occurs, while Π , T and E are learned from the students' observation sequence.

Conventional BKT assumes there are two types of hidden knowledge states ($N=2$) corresponding to student knowledge states of *unlearned* and *learned*. It also assumes there are two types of student observation ($M=2$) corresponding to student performance of *incorrect* and *correct*. BKT makes two assumptions about its conditional dependence as reflected in the edges in Figure 4. The first assumption BKT makes is a student's knowledge state at a time t is only contingent on her knowledge state at time $t - 1$. The second assumption is a student's performance at time t is only dependent on her current knowledge state. These two assumptions are captured by the state transition probability T and the emission probability E . In the context of student learning, BKT further defines five parameters:

Prior Knowledge = $P(S_0 = \text{learned})$
Learning Rate = $P(\text{learned} | \text{unlearned})$
Forget = $P(\text{unlearned} | \text{learned})$
Guess = $P(\text{correct} | \text{unlearned})$
Slip = $P(\text{incorrect} | \text{learned})$

In order to apply BKT to our dataset, we captured and mapped all students' actions based on the learning opportunities of knowledge components (KCs) step by step. For each of the KC, the Baum-Welch algorithm (or EM method) is used to iteratively update the model's parameters until a maximized probability of observing the training sequence is achieved.

3. EXPERIMENTS

In this work, we explored different student modeling tasks based on characteristics of two different learning environments. One was the task of early prediction of student success in an open-ended, self-paced programming environment while the other is the task of early prediction of student learning gains within a tutor-paced probability tutor.

3.1 Predicting Student Success on iSnap

3.1.1 iSnap

iSnap¹ is an extension to Snap! [15], a block-based programming environment, used in an introductory computing course for non-majors in a public university in the United States [37]. iSnap extends Snap! by providing students with data-driven hints derived from historical correct student solutions [36]. In addition, iSnap logs all students actions while programming (e.g. adding or deleting a block), as a *trace*, allowing us to detect the sequences of all student steps, as well as the *time* taken for each step. In this work, we focused on one homework exercise named Squirrel, derived from the BJC curriculum [15]. In Squirrel, students are asked to write a procedure that draws a square-like spiral. As shown in Figure 5, correct solutions require procedures, loops, and variables using at least 7 lines of code. We collected students' data for Squirrel from Spring 2016, Fall 2016, Spring 2017, and Fall 2017. We excluded students who requested hints from iSnap to eliminate factors that might affect students' problem-solving progress, leaving a total of 65, 38, 29,

¹All tutors and assignments names have been blinded for anonymous review

and 39 student code traces from each semester, respectively. The detailed statistics for iSnap dataset are shown in Table 1.

The data collected from iSnap consists of a code trace for each student's attempt. This code trace represents a sequence of timestamped snapshots of student code. We used an expert feature detector (EFD), described in [49], that automatically detects 7 features of a correct solution in a student snapshot. For example, for each snapshot in a student code trace, the EFD outputs a *feature state*, which is a series of 0s and 1s (e.g. 10000001) indicating the absence or presence of each feature, such that *feature-state: 10000001* shows that feature 1 and feature 7 are present, while the other 5 features are not. We ran the expert-feature detector to tag each snapshot in all 171 code traces, making a total of 31,064 tagged snapshots.

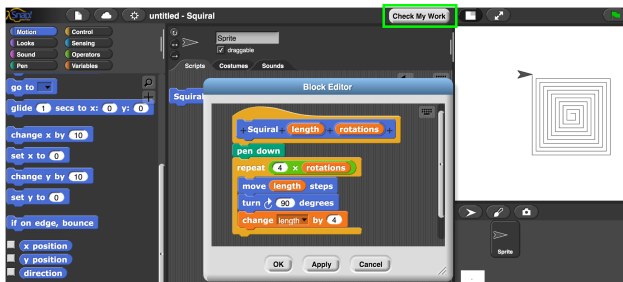

Figure 5: The iSnap interface, with the blocks palette on the left, the output stage on the right, the scripting area in the middle, and the hints button on top.

3.1.2 Student Success

In the context of iSnap, all the models were measured on the task of predicting student success. We classify the students who finished the programming assignment in one hour or less and got full credit as *successful* and labeled with “0”, those who either failed to complete or submit the assignment within one hour as *unsuccessful*, labeled with “1”. The one-hour cutoff was chosen based on a distribution showing that the vast majority of students (around 94%) who complete the assignment with full credit do so within one hour. Thus, each *trajectory* is assigned one ground truth label based on whether the student finished the assignment successfully or unsuccessfully. As a result, we refer to this task as the early prediction task for student success. Based on this definition, 59 of 171 students are in the *successful* group, and the remaining 112 are in the *unsuccessful* group. Note that this is a homework assignment that counts for only a small portion of a student's overall grade, and this behavior (of not attempting to obtain full credit) is typical in this introductory level.

To predict student success, we are given the first *up to n minutes* of a student's sequence data and our goal is to predict whether the student will successfully complete the programming assignment at any given point in the remainder of the sequence. To conduct this task, we left-aligned all the students' trajectories by their starting times and our *observation window* (the part of data used to train and test dif-

ferent machine learning models) includes the sequences from the very beginning to the first *n* minutes. If a student's trajectory is less than *n* minutes, our observation window will include their entire sequence *except* the last one.

3.1.3 Four Models

In the task of early prediction of student success, we have four models involved: Logistic Regression (LR), RTP, LSTM and T-LSTM. Note that BKT is not included here because for the open-ended domain like iSnap, there are no predefined steps or knowledge components that students must achieve to complete a given program. Thus, it is hard to map student actions on iSnap to learning opportunities defined in BKT.

Logistic Regression (LR): Since LR do not handle sequence data directly, we used a “Last Value” approach to treat the last measurement of each attribute within the given observation window as the input to train models. For early prediction settings, we truncated all the sequences in the training dataset in the same fashion as the testing dataset and then applied the Last Value approach on the truncated training dataset. For example, when our observation window is 6 minute, we apply the last value before 6 minutes for each sequence and treat them as inputs for LR.

RTP: For the RTP-based model, we first used RTP mining to generate the binary matrix and then applied LR to learn from the generated binary matrix. For early prediction, we only apply the *truncated* training sequences included in observation window to find RTPs. For example, for our 6-minute observation window, only the first 6 minutes of sequences were used for pattern extraction.

LSTM and T-LSTM: For LSTM the input is a multivariate temporal sequence from student work, and the output from the last step is used to make a prediction. While for T-LSTM, we also feed it with another sequence indicating time intervals for each student. As shown in Table 1, the time intervals of iSnap range from 1 to 291 seconds across four semesters, with $\mu = 0.613$ and $\sigma = 0.217$ for the overall decayed intervals. For both LSTM and T-LSTM, we used one hidden layer with 128 hidden neurons and set the maximum length to accommodate the longest sequence in our data. Typically for deep learning models, the whole multivariate time series from student sequence data is used as input data. However, for early prediction, only those events happening within our observation window from each sequence were used.

3.2 Predicting Learning Gains on Pyrenees

3.2.1 Pyrenees

Pyrenees is a web-based ITS teaching probability, which covers 10 major knowledge components (KCs), such as the Addition Theorem, the Complement Theorem, and Bayes' Rule, etc. Domain experts both identified the 10 KCs and labeled each step/exercise with the corresponding KCs, kappa > 0.9. Figure 6 shows the interface of Pyrenees which consists of a problem statement window, a variable window, an equation window, and a tutor-student dialogue window. Through the dialogue window, Pyrenees provides messages to the students. It can explain a worked example or prompt

Table 1: Detailed data statistics for iSnap, including total steps, total time spent in minutes, time intervals in seconds, corresponding decayed time intervals, and the success labels distribution for each of the four semesters.

Semester	Total Steps				Total Time (minutes)				Time Intervals (seconds)				Decayed Time Intervals		Success Labels	
	min	max	median	mean(std)	min	max	median	mean(std)	min	max	median	mean (std)	mean(std)		S	U
S16	10	1024	169	199 (175)	0.533	95.667	20.733	22.777 (17.149)	1	209	2	6.739 (13.75)	0.628 (0.217)		23	42
F16	28	884	121	167 (168)	3.283	119.083	16.325	22.379 (24.177)	1	189	3	7.919 (14.12)	0.594 (0.217)		15	23
S17	15	439	75	112 (94)	2.817	62.983	14.167	16.347 (11.872)	1	177	3	8.512 (16.14)	0.599 (0.225)		12	17
F17	10	2276	100	219 (376)	1.65	189.667	19.1	28.224 (33.869)	1	291	3	7.597 (15.61)	0.609 (0.215)		9	30

the student to complete the next step. Students can enter their inputs in the text area. Any variable or equation that is defined through this process is displayed on the left side of the screen for reference. Pyrenees can also provide on-demand hints. The bottom-out hint tells the student exactly how to solve a problem. Different from iSnap, the Pyrenees tutor provides immediate feedback for correct/incorrectness whenever an answer is submitted.

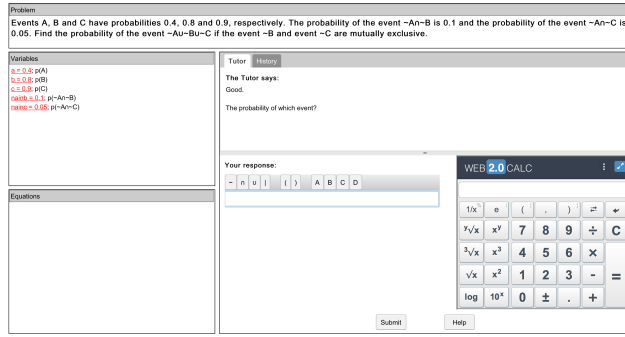

Figure 6: The Pyrenees interface, with the problem statement on the top, the variable window in the middle, the equation window at the bottom, and the dialog window on the right.

When training on Pyrenees, students were required to complete 4 phases: 1) pre-training, 2) pretest, 3) training, and 4) post-test. During the pre-training phase, all students studied the domain principles from a probability textbook. The students then took a pretest which contained 10 problems. The textbook was not available. Students were not given feedback on their answers, nor were they allowed to go back to earlier questions. During the training phase, students received the same 12 training problems in the same order on Pyrenees. Each domain concept was applied at least twice. The minimum number of steps needed to solve each training problem ranged from 10 to 50. The number of domain principles required to solve each problem ranged from 3 to 10. Finally, all of the students took a post-test with 20 problems. Both pretests and post-tests were graded in a double-blind manner by a single experienced grader (not the authors), and were normalized in the range of [0,1]. We collected six semesters of data from Pyrenees, including Fall 2016, Spring 2017, Fall 2017, Spring 2018, Fall 2018, and Spring 2019. The overall dataset comprises 102,948 data points from 1190 students, with 207, 159, 215, 161, 261 and 187 from each semester, respectively. The detailed statistics for Pyrenees dataset are shown in Table 2.

3.2.2 Quantized Learning Gain

In the context of Pyrenees, we applied all the models for student learning gains prediction. The concept of *learning gain* is formally defined as the difference between the skills, competencies, content knowledge and personal development demonstrated by students at two points in time [28]. we used a qualitative measurement called *Quantized Learning Gain* [24, QLG] to determine whether a student has benefited from our learning environment. QLG is a *binary* qualitative measurement on students' learning gains from pretest to the posttest: high vs. low. To infer QLGs, students were split into "low", "medium", and "high" based on whether they scored below the 33rd percentile, between the 33rd and 66th percentile, or higher than the 66th percentile in pre-test and post-test respectively. Once a student's pre- and post-test performance groups are decided, the student is a "high" QLG if he/she moved from a lower performance group to a higher performance group from pre-test to post-test or remained in "high" performance groups; whereas a "low" QLG is assigned to the student if he/she either moved from a higher performance group to a lower performance group from pre-test to post-test, or stayed at a "low" or "medium" groups (as shown in Figure 7). In Figure 7, solid lines represented the formation of the *high* QLG groups and dashed lines represents the formation of the *low* QLG groups, and they will be coded with "1" and "0" respectively for QLG prediction. As a result, we have 487 of 1190 students in the *high* learning gain group, and the remaining 703 students in the *low* learning gain group.

Figure 7: Quantized Learning Gain

Students usually need to spend 2-4 hours to complete the Pyrenees tutor. Thus we are given the first *up to n percent* of a student's sequence data to predict student QLG, and our goal is to predict whether the student will benefit from our tutoring system in the end. As with the success prediction in iSnap, we left-aligned all the students' trajectories by their starting times and our *observation window* includes the data from the very beginning to the first *n* percent of the whole sequence.

Table 2: Detailed data statistics for Pyrenees, including total steps, total time spent in hours, time intervals in seconds, corresponding decayed time intervals, and the QLG labels distribution for each of the six semesters.

Semester	Total Steps				Total Time (hours)				Time Intervals (seconds)				Decayed Time Intervals mean (std)	QLG Labels	
	min	max	median	mean(std)	min	max	median	mean (std)	min	max	median	mean (std)		low	high

3.2.3 Four Models

In the task of early prediction of student QLG, we have four models involved: LR, BKT, LSTM and T-LSTM. Note that we do not compare RTP here because, in Pyrenees, students’ responses are determined not only by their underlying knowledge state, but also by the pre-designed turn-taking nature of the system, which could obscure the temporal patterns found by RTP.

Logistic Regression (LR): As with student success prediction, the “Last Value” approach was applied to the non-temporal LR for the task of predicting student learning gains, as well as the early prediction setting. For example, when the training data is the *first 30% sequence*, only the last value before 30% of each sequence was applied for both training and testing.

BKT: To train the BKT model for QLG prediction, two steps were involved. In the first step, the probability of a student being in the *learned* state on each KC at the last attempt was learned from the BKT model. And in the second step, the output of the first step was computed as features for our prediction tasks. That is, the number of features involved here equals to the total number of KCs involved. The logistic regression was applied to predict QLG. As with early prediction setting of student success, only the *truncated* training sequences were applied to learn student learning probabilities from BKT.

LSTM and T-LSTM: In order to better compare LSTM and T-LSTM performance with BKT, the same two types of features were applied here for QLG prediction: 1) the assignment of KCs corresponding to each step, and 2) student performance at each step, i.e, correct or incorrect. As shown in Table 2, the time intervals of Pyrenees range from 1 second to 14 days across the six semesters, with $\mu = 0.307$ and $\sigma = 0.107$ for overall decayed intervals. For both LSTM and T-LSTM, we used one hidden layer with 64 hidden neurons and also set the maximum length to accommodate the longest sequence in our data. Again, only those events happening within our observation window from each sequence were applied for training and testing of early prediction.

3.3 Evaluation Metrics

Our models in this work were evaluated using Accuracy, Precision, Recall, F1 Score, and AUC (Area Under ROC curve). Accuracy represents the proportion of students whose labels were correctly identified. Precision is the proportion of students who were predicted to be successful by each model who were actually in the *successful* (or *high* QLG) group. Recall tells us what proportion of students, who will actu-

ally be unsuccessful (or in *low* QLG group), who were correctly recognized by the model. F1 Score is the harmonic mean of Precision and Recall that sets their trade-off. AUC measures the ability of models to discriminate groups with different labels. Given the nature of the tasks, we mainly use Accuracy and AUC to compare different models. Finally, it is important to emphasize that all models were evaluated using semester-based temporal cross-validation for both tasks, which just applied data from previous semesters for training and is a much stricter approach for time series data than the standard cross-validation.

4. RESULTS

4.1 Predicting Student Success in iSnap

Table 3 shows the performance of all models using the first-6-minute training sequences to predict students’ success in the programming task. The first column indicates the models including majority baseline model using simple Majority vote, Logistic Regression (LR), RTP, LSTM and T-LSTM. Columns 2-5 report all of the models’ performance for the first-6-minute observation window. We evaluated the models on different metrics including Accuracy, Precision, Recall, F1 and AUC score; note that we ignored the Precision, Recall and F1-measure of the simple Majority baseline. The last column reports the mean AUC score of all models from 0 - 20 minutes, with standard deviations between brackets. At first-6-minute, we can observe that T-LSTM outperforms all the other models and it contributes the highest score on every measurement except that the best Recall comes from RTP. LSTM and RTP have very similar performance at first-6-minute, and both of them get better performance than LR except on Precision and AUC. On the other hand, when comparing the overall AUC score among all the models, T-LSTM still achieves the highest score. These results suggests T-LSTM can better learn the difference between successful/unsuccesful groups with the help of time-awareness.

Figures 8 (a) and (b) report Accuracy and AUC performance respectively for all models predicting student success. For each graph, we vary the observation window from the first 2 minutes up to 20 minutes. As shown in Table 1, students generally take 10 to 60 minutes to complete the task and thus we took a measurement every 2 minutes for the first 10 minutes to generate the early stage predictions for each model. T-LSTM is in red, LSTM in blue, RTP in purple, LR in green, and majority baseline in black. Both Figures 8 (a) and (b) show that T-LSTM was the best model for student programming success prediction as it stays on the top across all sizes of the observation window. It is not surpris-

Table 3: iSnap Student Success Prediction at First-6-minute and Overall Time (0 - 20 minutes)

Models	first-6-minute					Overall
	Accuracy	Precision	Recall	F1-measure	AUC	AUC
Majority	0.6604	-	-	-	0.5000	0.5000
LR	0.6038	0.8333	0.5000	0.6250	0.6528	0.7123(± 0.08)
RTP	0.6792	0.7195	0.8429	0.7763	0.6020	0.6948(± 0.09)
LSTM	0.6792	0.7368	0.8000	0.7671	0.6222	0.6755(± 0.09)
T-LSTM	0.7358	0.875	0.7000	0.7778	0.7528	0.7512(± 0.07)

Note: best model on each metric in **bold**

ing that generally for all the models (except majority baseline), the longer the observation windows, the better performance. This is because the training data includes more and more information and students get closer to their final state. The fact that the best prediction comes from T-LSTM really suggests that during the self-paced programming task, taking time-awareness into consideration brings us closer to the truth of the student learning process, especially for the early stage (first 10 minutes). However, this is only one observation from one programming task and more research is needed to understand the full nature of the benefits of time-awareness.

4.2 Predicting Learning Gains in Pyrenees

Table 4 shows the performance of all models using the first-30%-sequence to predict students' QLG on the probability tutor. The first column indicates the models including majority baseline model using simple Majority vote, LR, BKT, LSTM, and T-LSTM. Columns 2-5 report the all of the models' performance at the first-30%-sequence observation window. As with Table 3, we evaluated the models on Accuracy, Precision, Recall, F1 and AUC score and ignored the Precision, Recall and F1-measure for the simple Majority baseline. The last column reports the mean AUC score of all models from 0 - 100% sequence, with standard deviations between brackets. When only applying the first-30%-sequence, T-LSTM generates the best performance on every measurement except Recall and F1, where the best Recall is from LR and best F1 from LSTM. Comparing the two deep learning models with classic BKT, we can observe that both LSTM and T-LSTM outperform BKT across all metrics. For the overall AUC performance, LSTM and T-LSTM have very similar scores and are equally good. And still, they achieve higher mean AUC scores than BKT, with a lower standard deviation. Despite the similar overall performance from the two deep learning models, the better early prediction of T-LSTM suggests that time-awareness can help to understand student learning states earlier.

The early prediction results for student learning gains in probability are reported in Figure 9. BKT is in purple, and as in Figure 8, T-LSTM, LSTM, and LR are in red, blue and green, respectively. For each graph, the results are measured at every 10% increment of the sequence length. Generally speaking, the three models (BKT, LSTM and T-LSTM) generate better results as the sequence length increases. Both Figures 9 (a) and (b) show that the two deep learning models outperform BKT for probability, no matter on Accuracy or AUC score. While between LSTM and T-LSTM, there is not a clear winner. Sometimes T-LSTM gets better per-

Figure 8: Student Success Early Prediction on iSnap

Table 4: Pyrenees Student QLG Prediction at First-30%-minutes and Overall Time (0 - 100%)

Models	first-30%-sequence					Overall AUC
	Accuracy	Precision	Recall	F1-measure	AUC	
Majority	0.5860	-	-	-	0.5000	0.5000
LR	0.5839	0.5893	0.9566	0.7293	0.5066	0.4957(± 0.01)
BKT	0.6022	0.6113	0.8819	0.7221	0.5442	0.5690 (± 0.03)
LSTM	0.6226	0.6188	0.9271	0.7422	0.5594	0.6013 (± 0.02)
T-LSTM	0.6328	0.6322	0.8924	0.7401	0.5789	0.5950 (± 0.02)

Note: best model on each metric in **bold**

formance on Accuracy (from 10% to 30%) while sometimes LSTM slightly outperforms T-LSTM (from 40% to 70%). Overall, LSTM and T-LSTM generate very similar results on predicting student QLG; and T-LSTM generally has better performance on the very early stage.

5. RELATED WORK

Student modeling has been widely and extensively explored in previous research. For example, prior research has proposed a series of approaches based on logistic regression including Item Response Theory (IRT) [42], Learning Factor Analysis [5], Learning Decomposition [4], Instructional Factors Analysis [7], Performance Factors Analysis [33], and Recent-Performance Factors Analysis [14]. These models were implemented with different parameters to better understand and model student learning and were shown to be very successful.

BKT [10] is one of the most widely investigated student modeling approaches. It models a student's performance in solving problems related to a given concept using a binary variable (i.e., correct, incorrect) and continually updates its estimation of the student's learning state for that concept. Many extensions of BKT have been proposed to capture the complex and diverse aspects of student learning. Pardos and Heffernan [31] explored individualized prior knowledge parameters based on students' overall competence. Their results showed that the proposed model outperformed conventional BKT in predicting students' responses to the last question at the end of the entire training. They later introduced problem difficulty to BKT and found substantial performance improvement in predicting student step-by-step responses over BKT [32]. Additionally, Yudelson et al. [48] parameterized student learning rates in BKT models and the results showed that the new model outperformed conventional BKT in predicting whether the students' next responses were going to be correct/incorrect. Baker et al. [1] investigated contextualized guess and slip rates to deal with the issues of identifiability and model degeneracy commonly observed in conventional BKT. Their results suggested that the proposed models achieved better performance in predicting students' next-step response than BKT. However, in this study, BKT-based models cannot be directly applied to our open-ended programming tasks, because of the adversity of mapping students' time-various actions step by step.

In recent years, extensive research has been conducted on deep learning models, especially Recurrent Neural Networks (RNN) or RNN-based models such as LSTM. These deep recurrent models have shown great success in many domains

such as speech recognition [17], language translation [26], video classification [29], and rainfall intensity prediction [46], etc. Their success in all these domains has opened up a new line of research in educational data mining [35, 41, 22, 45, 47, 24, 30]. Mao et al. [27] have shown that LSTM has superior performance on the early prediction of student learning gains compared with classic BKT-based models. For the task of predicting students' responses to exercises, LSTM was shown to outperform conventional BKT [35] and Performance Factors Analysis [33]. However, RNN and LSTM did not always have better performance when the simple, conventional models incorporated other parameters. For example, Khajah et al. [22] investigated what statistical regularities neural networks can exploit that BKT cannot, and showed that BKT with relaxed assumptions can outperform LSTM. Wilson et al. [45] also show that Bayesian extensions of simple IRT-based models are also equal to or outperform RNN-based models on a variety of datasets.

While most of the previous studies on student modeling focus on predicting students' success and failure in the next-step attempt, some research has used student-tutor interaction data to predict student post-test scores [13, 39]. In this work, we explored the early prediction of student success and learning gains for a computer-based programming system and an intelligent tutoring system, respectively.

6. CONCLUSIONS

Early prediction of student learning state is a crucial component of student modeling, since it allows tutoring systems to intervene by providing needed support, such as a hint, or by alerting an instructor. Both prediction tasks involved in this work are challenging because: 1) the open-ended nature of iSnap hinders the prediction of student final success, and 2) it is extremely hard to track whether a student benefits from a tutoring system or not even in a well-defined domain like Pyrenees. In this work, we investigated the effectiveness of a time-aware model, T-LSTM on the two different prediction tasks and compared it with other student modeling methods including LSTM, RTP, logistic regression models, and BKT. Our results show that T-LSTM consistently outperforms the other models such as LSTM, RTP, and non-temporal logistic regression on the task of predicting student success in iSnap, at all observation windows from first 2 minutes to 20 minutes. On the other hand, for the task of predicting student learning gains in Pyrenees, T-LSTM does not outperform the other models. More specifically, T-LSTM outperforms LSTM and BKT on the early stage with only 30% of the student sequences, and afterward time-awareness does not help much when more data is available. One possible explanation behind this is that in a well-defined domain, the whole learning process is mainly driven by the tutor, which makes the elapsed time less important to student learning gains especially when the step-level performance is available. However, in the open-ended programming environment, students are self-prompted to complete an assignment; and therefore the amount of time they stayed in a state really matters to understand their learning. And therefore, T-LSTM can generate better performance by modeling the student dynamics of knowledge *in continuous time* than other methods in *discrete timesteps*.

One limitation of this work is that we only explored one im-

portant student modeling task in each learning environment. An important direction for future work is to investigate the time-aware model on other student modeling tasks in both learning environments to determine whether the same results will hold. In addition, we are planning to employ the time-awareness to other models such as RTP to explore whether it continues to support improvement for the open-ended programming environment. Also, this work will be applied to larger groups of students and longer programming tasks, along with integration of more informative features such as intervention and demographic features to develop more robust models. Additionally, we plan to expand our evaluations to longer programs with more complex constructs from both text-based and block-based programming languages.

ABSTRACT

In some computerized educational systems, there is evidence of students *wheel-spinning*, where a student tries and repeatedly fails at an educational task for learning a skill. This may be particularly concerning in low resource settings. Prior research has focused on predicting and modeling wheel-spinning, but there has been little work on how to best help students stuck in wheel-spinning. We use past student system interaction data and a minimal amount of expert input to automatically inform individualized interventions, without needing experts to label a large dataset of interventions. Our method trains a model to predict wheel-spinning and utilizes a popular tool in interpretable machine learning, Shapley values, to provide individualized credit attribution over the features of the model, including actionable features like possible gaps in prerequisites. In simulation on two different statistical student models, our approach can identify a correct intervention with over 80% accuracy before the simulated student begins the activity they will wheel spin on. In our real dataset we show initial qualitative results that our proposed interventions match what an expert would prescribe.

Explainable Machine Learning, Inferring Interventions, Wheel-Spinning, Feature Attribution, Shapley Values

1. INTRODUCTION

Educational technology is increasingly used in a wide array of K-12 settings and some students struggle. Beck et al. [6] coined the term “wheel-spinning” to denote students that were repeatedly trying, and failing, to successfully complete a specific skill after many attempts in an intelligent tutoring system. They additionally found it was a significant issue in two popular computerized educational systems. Such long repeated failures are likely to be an inefficient use of time for students, and may additionally contribute to lack of motivation for future learning.

Although expert human instructors are often very good at diagnosing and assisting students who are stuck, it is time consuming for both the instructors and the students waiting for the instructor’s intervention. Additionally many educational settings lack a sufficient number of expert teachers. Our research is particularly motivated by a collaboration with the non-profit War Child Holland whose program Can’t Wait to Learn (CWTL) provides self-paced educational software on tablets primarily to children in or coming from conflict-affected regions. In such settings, a limited number of teachers must often address the learning needs of a large number of students with a wide variety of educational backgrounds. To give a specific example, in the classes in Uganda the program is implemented in, the average class size is 114 students per teacher. Additionally for some population of students where education is especially hard to access, the program is run by facilitators who do not have the same expertise as instructors to provide learning support for individuals. Methods that can automatically identify individualized interventions, such as having the student practice an activity to review a prerequisite skill, to help wheel-spinning students could be greatly beneficial for students and teachers. However, since the term was coined, there has been much work for modelling and predicting wheel-spinning [11, 12, 16], but little work in developing interventions.

There are many possible reasons a student may wheel-spin, including lack of required prior knowledge, a long gap in learning of the material, or an ineffective educational activity. One approach could be to have experts label a large dataset with expert prescribed interventions and train a model to predict those interventions. However in many cases the time necessary to label such a dataset can be infeasibly large. For example, in our real world dataset a domain expert needed 30 minutes to label the 6 wheel-spinning cases we use for a qualitative evaluation. This would translate to 120 expert hours to label our whole dataset of more than 2000 wheel-spinning cases.

In this work we present a method to automatically predict when an intervention could be helpful and which intervention to give. Our method uses prior student system log data and only requires a few hours of expert input. Our method takes as input a set of features, a subset of which are actionable and correspond to a concrete intervention (for example, the feature “prerequisite performance” could correspond to an intervention of reviewing that prerequisite). We then use featurized past student data to train a model

Tong Mu, Andrea Jetten and Emma Brunskill "Towards Suggesting Actionable Interventions for Wheel Spinning Students" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 183 - 193

to predict wheel-spinning. With the prediction model, we use methods from explainable machine for providing feature credit attribution for the prediction of individual datapoints, specifically Shapley values [19], to determine which actionable feature contributed most to the prediction and suggest an intervention.

We evaluate the ability of our method to suggest correct interventions through simulation and through a qualitative study with our real data. Evaluating if our method is impactful will eventually require experimental studies. The costs of an experiment are high in our situation where this educational technology is being used by children in conflict-affected areas and who may be in remote villages without internet. Before embarking on such an effort, in this work we first assess the potential benefits and performance of our method. In simulation studies, we simulated students using two different student models, both based on the popular Bayesian Knowledge Tracing (BKT) [10] student model. In both of our simulations, our method can prescribe a correct action (a helpful intervention or correctly identifying no intervention is needed) with high accuracy before attempting an activity. This accuracy can be improved if the prediction is made at a later attempt. In an initial qualitative assessment in our real world CWTL setting we show our method's explanations are consistent with what an expert would prescribe in a majority of the cases. In the other cases the method did not have access to key data used by the expert, suggesting our method is able to identify correct interventions over correctly defined inputs.

Our method is, to our knowledge, one of the first works for both addressing automatically identifying interventions for wheel-spinning students and using interpretable machine learning in educational technologies. These results suggest that our method can help inform interventions, whether for carefully designed human-in-the-loop systems (such as only informing the teacher if confident the teacher is the best source) or for automated systems (jumping back to practice an earlier skill), and may help further adaptive automated systems for effective, efficient and engaging education.

2. RELATED WORKS

2.1 Wheel-Spinning

The term *wheel-spinning* was first coined by Beck et. al [6] where they examine its prevalence in two educational systems. Gong et al.[11] further explored models to predict wheel-spinning. Beck et al [5] found it applied to students in non-western societies as well. They also examined the influence of affective factors, and found it correlated with gaming the system. Matsuda et al. [16] examined using neural networks together with the BKT model [10] to predict wheel-spinning using only past student performance information. Kai et al. [12] investigate using decision trees to distinguish between productive persistence and wheel-spinning. Zhang et al. [24] make a comparison over many methods for detecting wheel-spinning. Wan et. al [23] take a step in modeling with actionable results by examining the effects of using prerequisite performance as features. They modeled wheel-spinning using both the average prerequisite performance and the weakest prerequisite and found that prerequisite knowledge was a reliable predictor of wheel-spinning and slightly improved model performance. In our work we pro-

Feature	Abbrev	Value	Feature	Abbrev	Value
Activity ID	ID	31	# Attempts Prerequisite 1	P1	High
Time since last played	T	25	# Attempts Prerequisite 2	P2	High
# Attempts Prerequisite 1	P1	7	# Attempts Prerequisite 3	P3	High
# Attempts Prerequisite 2	P2	1

Figure 1: Simulated Student Setting

pose a method to not only predict wheel-spinning, but also give suggestion of a possible intervention. We achieve this by designing our features to be actionable, such as incorporating performance on all prerequisites as separate features, with methods from explainable machine learning.

2.2 Explainable Machine Learning

Explainable Machine Learning is a rapidly growing popular field in the machine learning community. One subfield is the study of feature attribution which are methods that return how much each feature contributed to the total prediction of a datapoint in a machine learning model. In our work we use Shapely values [19], and the python implementation SHAP [13, 14] package to inform interventions. Shapley values are a method originating in game theory for fairly allocating a payout between participants. It has recently found popularity in explainable machine learning to calculate feature attributions. Shapley values have been used widely both within and outside of machine learning, including in medical applications [15], social network node analysis [17], and studying carbon emission quotas in China [25]. To our knowledge this is one of the first works on using Shapley values and explainable machine learning methods for educational technologies.

3. METHODS

In this section we present an algorithm to help students likely to wheel spin by suggesting actionable interventions. Our goal is to provide a method for using past student log data to predict when and which intervention a student will need to prevent wheel-spinning. We would also like to minimize interruptions to student-activity pairs who do not wheel spin. Similar to prior work [6] we define wheel-spinning as when a student consecutively fails an educational activity more than a threshold number of times. We will refer to the student-activity pair of the i^{th} student working on the j^{th} activity as $pair_{ij}$. To achieve our goal, for every $pair_{ij}$, our algorithm uses a 2 level decision process shown in Algorithm 1.

We first train a machine learning model using an existing dataset of student log data to predict wheel-spinning. Our overall algorithm (Algorithm 1) is compatible with any machine learning model that outputs probabilities of wheel-spinning given an input set of student features. In our work we use the popular gradient boosting method XGBoost [9]. When a student is using the educational program, given their current state the algorithm uses the trained model to predict if a student-activity pair will result in wheel-spinning. We define the number of failed attempts a student

makes before we decide to possibly suggest an intervention as n . If the student has reached the n^{th} attempt on the current item our method uses the wheel-spinning model to predict if wheel-spinning will occur. If the output probability of wheel-spinning of the model is greater than a threshold, p , the algorithm will then propose a potential intervention. n and p are hyperparameters, and we provide further discussion on their effect in Sections 4.5 and 6.

Interventions are proposed using a method of feature attribution from explainable machine learning, Shapley Values [19] (described in more detail in Section 3.1). We use Shapley values to assign a contribution value to each feature used in the wheel-spinning prediction model. A subset of these features are designed to be actionable and correspond to an intervention. For example, Figure 1a shows example feature values of a fake datapoint for a student-activity pair inspired by CWTL. An example of an actionable feature in this fake datapoint is number of attempts required on a prerequisite skill. If assigned a high positive attribution value, it would suggest the student needs more practice on that prerequisite. Our method identifies the actionable feature with the highest Shapley value and suggests the corresponding intervention to give to the student. Non-actionable features that do not correspond to an intervention but increase prediction accuracy are also included.

There are a few places that require expert input, for example choosing hyperparameters n and p and designing the features and interventions. For experiments with our real world dataset, we worked together with a domain expert to create actionable features and corresponding interventions.

3.1 Background on Shapley Values

In this section we provide some background on the calculation and properties of Shapley Values [19] which is used in our method to provide feature attribution for the wheel-spinning prediction of individual datapoints. Shapley values originated in game theory and in the context of explainable machine learning, provide an attribution for how much each feature contributes to the total prediction of a datapoint. To give an example, consider a setting where we are predicting wheel-spinning using features in our dataset. We will refer to this setting as example setting 1. The datapoint in Figure 1a gives an example datapoint in this setting. Assume the mean prediction of the wheel-spinning model over all the datapoints in this example is 0.5, and for this datapoint the model predicts a probability of 0.8, which is +0.3 from the mean. The Shapley values for each feature give the contribution of each feature to this difference from the mean where the sum of contributions over all features must be +0.3. For example the features ID , T , $P2$ could all be attributed -0.1 and the feature $P1$ could be attributed +0.6. This attribution would suggest the value of the number of attempts on prerequisite 1 is likely to be responsible for the increased probability of wheel-spinning over the average wheel-spinning prediction.

Shapley values is the only method for attribution that satisfies the following desirable properties which together are the definition of a fair attribution [19]: symmetry (two features that contribute equally will have the same value), dummy (a feature that does not change the prediction has a value of

0), and additivity (if the prediction model is the sum of multiple models, the value of a feature in the prediction model is the sum of all values over the individual models). To give intuition of why the symmetry and dummy properties are desirable in this context, consider a second, simpler example setting, example setting 2, where we are also predicting wheel-spinning but all inputs and outputs are binary. In this setting the wheel-spinning prediction is for one activity that is thought to have three prerequisites ($P1$, $P2$, $P3$). Figure 1b gives an example datapoint in this setting. Consider the case where two prerequisites, $P1$ and $P2$, are equally important and $P3$ was incorrectly labeled as a prerequisite and its value never influences the prediction of the model. Because $P1$ and $P2$ are equally important and for the datapoint in figure 1b both their values are high, we would like them to have equal attribution, or to satisfy the “symmetry” property. Additionally, because $P3$ was incorrectly labelled as a prerequisite we would want it to be given 0 attribution regardless of its value, or to satisfy the “dummy” property.

We now describe formally how to calculate Shapley values. Let \mathcal{F} denote the set of features and X denote the dataset. One example of a datapoint in X from example setting 1 is the example datapoint Figure 1a, which we will refer to as x_i . In this example $\mathcal{F} = \{ID, T, P1, P2\}$. Also assume there is a function V where $V(x_i)$ is the predicted value on datapoint x_i . Let $SHAP(x_i, f_j)$ be x_i ’s Shapley value for feature f_j . In our example, $V(x_i)$ would output the probability of x_i wheel-spinning. For a subset of features s , ($s \subseteq \mathcal{F}$) we define a fake datapoint, $x_{i,s}$, as a datapoint that only includes the the values of x_i for the features in s . In our example, one potential s could be $\{T, P1\}$, and the corresponding $x_{i,s} = [T : 25, P1 : 7]$. For a feature f_j , we define a coalition of features, F , as a subset of \mathcal{F} that does not include f_j . We define \mathcal{C} as the set of all unique coalitions for f_j and let F_k denote the k^{th} coalition in this set. Let the contribution of f_j in coalition F_k to the prediction of x_i be the difference in prediction of the datapoint without f_j and the datapoint with f_j included, or $V(x_{i, F_k \cup f_j}) - V(x_{i, F_k})$. In our example, the $s = \{T, P1\}$ is a coalition of features for $f_j = ID$ as it does not include f_j . If the probability of wheel-spinning on $x_{i,s}$ ($V([T : 25, P1 : 7])$) is -0.1 and $V(x_{i, F_k \cup f_j}) = V([ID : 31, T : 25, P1 : 7]) = -0.2$. Then the difference $V(x_{i, F_k \cup f_j}) - V(x_{i, F_k}) = -0.1$

The Shapley value is then the expected contribution of f_j averaged over all coalitions:

$$\begin{aligned} SHAP(x_i, f_j) &= \mathbb{E}_{\mathcal{C}}[V(x_{i, F \cup f_j}) - V(x_{i, F})] \\ &= \sum_{F_k \in \mathcal{C}} \frac{|F_k|!(|\mathcal{F}| - 1 - |F_k|)!}{|\mathcal{F}|!} (V(x_{i, F_k \cup f_j}) - V(x_{i, F_k})) \end{aligned} \quad (1)$$

$$(2)$$

Going back to example setting 2 (Figure 1b), we see once either $P1$ or $P2$ enters a coalition that does not contain either of them (so $\{\emptyset\}$ or $\{P3\}$) the prediction increases from zero to one and will not increase further when the other enters. Because we average across all coalitions and in half of the coalitions, $P1$ will occur before $P2$ and in the other half $P2$ will occur before $P1$, the symmetry property will be

satisfied and $P1$ and $P2$ will be given equal attribution. We can also see that if $P3$ does not change the prediction value in any coalition, it will be given zero attribution, satisfying the dummy property.

In the machine learning case, we would like to use a machine learning model M as the function that assigns a predicted value to x_i . Because a machine learning model requires a datapoint to have values for all features, we must approximate $V(x_{i,F_k})$ using other datapoints. Let x_l be a randomly sampled real datapoint from the dataset that is not x_i . We define a fake datapoint $x_{i,F_k,l}$ as a hybrid datapoint that contains the feature values of x_i for the features in F_k and the feature values of x_l for the features not in F_k . In our running example, $x_{i,F_k,l} = [ID: x_{l,ID}, T: 7, P1:6, P2:x_{l,P2}]$. $M(x_{i,F_k,l})$ is then used to approximate $V(x_{i,F_k})$.

Shapley values require summing over all possible coalitions and are very computationally expensive. There are algorithms that compute an approximate solution through sampling such as the method proposed by Vstrumbel et al [20]. In our case, we use an implementation, TreeSHAP [13, 14], designed to efficiently and quickly calculate exactly Shapley Values for decision tree based models.

Algorithm 1: Suggest Intervention for $Pair_{ij}$

Input : Dataset of Preexisting Log Files (\mathcal{D}), Set of Actionable Features (\mathcal{F}_a), Set of other features (\mathcal{F}_o), Mapping of Actionable Features to Interventions (**GetIntervention**), $student_i$ log file (L_i) at n^{th} attempt on $problem_j$, wheel-spinning Model Output Probability Threshold (p)

Output: Suggested Intervention for $Pair_{ij}$

// We abbreviate wheel-spinning as WS

$WSModel = \text{TrainModel}(\mathcal{D}, \{\mathcal{F}_a, \mathcal{F}_o\}, n)$

$X_i = \text{GetCurrentFeatures}(L_i, \{\mathcal{F}_a, \mathcal{F}_o\})$

$q = WSModel.predict(X_i)$

if $q > p$ **then**

$\{SHAP_a, SHAP_o\} = \text{ComputeShapley}(X_i, WSModel, \{\mathcal{F}_a, \mathcal{F}_o\})$ // Section 3.1

$MaxFeature = \text{argmax}_{f_a} SHAP_a$

$Intervention = \text{GetIntervention}(MaxFeature)$

else

$Intervention = \text{Don't Intervene}$

end

3.2 Baselines

We compare to two baselines and, in this section, include discussion for building intuition for which situations our proposed method could outperform the baselines.

Baseline 1 - Overall Feature Importance (FI): Because we are using a decision tree based method to predict wheel-spinning, overall feature importances are calculated automatically. Therefore, we can consider a method that when a student-item pair is predicted to wheel spin, choose the intervention suggested by the feature with the highest overall feature importance. This method requires less compute as it does not require an additional step of calculating individualized feature attributions. Conceptually, this method will perform equivalently as our proposed method when there is

a single cause for wheel-spinning. However in cases where there can be many potential causes (for example, some student-item wheel-spinning is due to forgetting effects from long durations between learning while others are due to unmastered prerequisites), then this baseline, which will only select the single, most predictive cause for all students, will perform poorly. In this respect, this baseline has parallels to a baseline which predicts the majority class. Note that we do not compare to a baseline that predicts the majority class because we are considering a setting where we do not have any labels for wheel-spinning causes. Consequently our method has no way of discerning what the majority cause is. The goal of our work instead is investigating the effectiveness of feature attribution methods to identify causes.

Baseline 2 - Logistic Regression (LR): Linear models such as logistic regression are a computationally efficient subset of our method as they, by nature and without needing additional calculation, have feature credit attribution for the predictions of individual datapoints. They can potentially work well in cases where a linear relationship can accurately model the relation between features and wheel-spinning. However in many domains, such as CWTL, non-linear models for the wheel-spinning prediction can achieve better performance (shown in Section 5.4). Therefore in this work we focus on a method that can work with non-linear models and we treat linear models as a baseline.

4. SIMULATIONS

We assess the performance of our method in simulation where we can create true causes of wheel-spinning, which we define as needing 10 or more attempts on one educational activity to match both prior work [11, 12] and evidence from the CWTL data.

We simulate students using two different student models both based on the Bayesian Knowledge Tracing (BKT) model [10]. The BKT model is a two state Hidden Markov Model (HMM) and is a popular model of student learning that has been shown to be successful for various applications in the educational technology literature (for example Corbett et al. [10]). The model has two hidden states, mastered or not mastered, and two observed states, correct or incorrect. From the mastered state of a skill, the student will answer an educational activity involving that skill correctly unless they slip and answer incorrectly with a probability of slip ($P(s)$). From the unmastered state of that skill, a student will answer a problem involving the skill incorrectly, unless they guess correctly with a probability of guess ($P(G)$). Everytime the student is presented a practice opportunity for an unmastered skill, they have a probability of transitioning ($P(T)$) to the mastered state for the skill. We make modifications to the BKT model to match aspects of the CWTL domain that may also occur in other domains. In our simulations we specifically consider a situation where a student may have been moved on too fast because they passed a prerequisite by guessing. This is because the corresponding intervention of reviewing the relevant prerequisite could be automated and is a key feature we are trying to achieve in the CWTL setting.

4.1 Simulated Curriculum

In Figure 2a we illustrate our simulated sequence of educational activities as well as the prerequisite structure between them. In this setting we consider each activity as corresponding to a unique skill. Skills build on each other in the way shown in the prerequisite graph. To mimic the CWTL curriculum, simulated students are presented educational activities in order starting at A1. They are repeatedly presented an educational activity (for example A1) until they succeed and are moved onto the next activity (in our example, A2).

We note that while our analysis and results are in a setting where the curriculum is linear, our method does not rely on this setting and can be applied more generally to different types of ordering constraints over educational activities.

4.2 Student Model 1

In our first student model, we make two modifications to the BKT model to reflect behaviors that occur in our domain and in other domains. In CWTL, each activity involves answering a certain percentage of multiple choice questions relating to the target skill of the activity correctly. In this setting, the probability of guess starts low, however questions are reused between activity instances so the probability of guess increases with attempts as students may start to memorize answers. This effect can also occur in other domains where questions are reused. To mimic this effect in simulation, we start the probability of guess at a low base value $P(G)$ and with every attempted answer by the student, we increase it in such a way that at the n^{th} attempt of the student on the problem the probability of guess, $P_n(G)$, is $P_n(G) = 1 - (1 - P(G))^n$. We use this function as it monotonically increases to its limit of 1.

Our second modification is, for skills involving prerequisites (A4 and A5), we enforce the prerequisite structure by defining a new transition probability for when the prerequisites are not mastered, $P_{unmastered}(T)$. In all our simulations this was set to zero however this probability can also be set to a small non-zero probability with similar results. This is to reflect the difficulty of learning complex combinatorial skills without mastering the prerequisites.

4.2.1 Data Generation

In our simulations, we show our method is able to correctly distinguish when and which prerequisite should be reviewed. We consider the whole population comprised equally of two different populations of students. Students of student population 1 finds all skills “easy” to master and has high transition probabilities for all skills. Students of student population 2 finds one of the prerequisite skills (A1, A2, or A3) “hard” to master and has low transition probabilities for that skill. For this student model, we are able to control which prerequisite students of student population 2 may not master by setting that prerequisite as “hard”. Additionally we can examine the performance of our method at suggesting interventions in a heterogeneous population.

We report results from one set of parameters with the transition dynamics described in Table 1. Notice $P(G)$ is lower for A4 and A5 to reflect the complexity of those two questions over A1, A2, and A3. We generate both our training and test sets by simulating 1000 student trajectories, 500 from

Table 1: Parameters for Student Model 1

P(T) “easy”	P(T) “hard”	P(G) (A1,A2,A3)	P(G) (A4,A5)	P(S)	“hard” skill
0.5	0.01	0.01	0.005	0	A2

Table 2: Parameters for Student Model 2

P(T)	P(D)	P(G) (A1,A2,A3)	P(G) (A4,A5)	P(S)
0.5	0.1	0.01	0.005	0

each population. For these simulation parameters, initially $P_{easy}(T)$ is higher than $P_n(G)$ and if a student needs a low number of attempts on a prerequisite, they are most likely part of student population 1 and have mastered the prerequisite. If a student needs a higher number of attempts on a prerequisite, then they are most likely in student population 2 and they may either have mastered the prerequisite or passed through guessing and need to repractice the prerequisite. Decreasing the value of $P_{easy}(T)$ or $P(G)$ can increase the strength of this correlation between attempts and mastery and allow model accuracy to increase. Similarly, increasing these parameters, or increasing $P_{unmastered}(T)$ can decrease accuracy.

4.3 Student Model 2

We designed our second simulated model to account for student engagement and simulate disengagement and wheel-spinning behavior. We did so based on expert insights, and findings from prior literature on boredom and disengagement in tutoring systems. A figure illustrating this modified model is shown in Figure 2b.

In this model we make an additional modification on Student Model 1 by splitting the “Not Mastered” state into two states: “Engaged” and “Disengaged”. Each student for each activity starts in the Engaged state. In the Engaged state the student is open to learning and can transition to the “Mastered” state with probability $P(T)$. However with each failed activity attempt, on the n^{th} attempt they can also transition to the “Disengaged” state with probability $P_n(D)$. This probability of disengagement starts at 0 and is parametrized by a base value of $P(D)$. It increases monotonically in the same way the probability of guess does, to eventually reach 1: $P_n(D) = 1 - (1 - P(D))^n$. Once in the disengaged state for a skill, the student can transition out of it with probability $P(E)$. In our simulations we set $P(E)$ to 0 however it can also be set to a small non-zero probability with similar results.

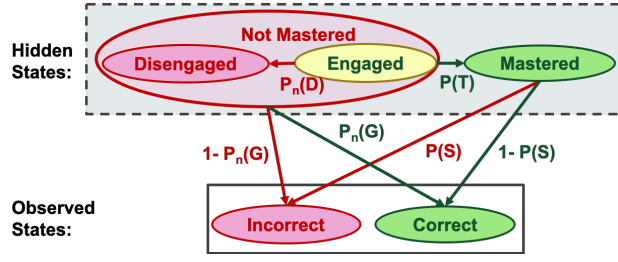

We make these modifications to reflect points from (1) prior literature and from domain expert insights that suggests repetitive tasks can lead to boredom [22, 8], (2) literature suggesting boredom can lead to disengagement which results in gaming behavior (such as random guessing) [3, 2, 4, 1, 11] as opposed to productive learning (3) literature suggesting disengagement and boredom are affective states that persist and are hard to transition out of [4, 1, 18].

4.3.1 Data Generation

We generate both our training and test set by simulating and generating 1000 student trajectories. Parameters used

(a) Simulated Curriculum

(b) Diagram of the modified BKT of Student Model 2

Figure 2: Simulated Student Setting

to generate the results are given in Table 2. For these parameters because $P(T)$ is initially much higher than $P_n(G)$ and $P_n(D)$, if a student needs a low number of attempts, they most likely mastered the activity. If they need a large number of attempts, they most likely became disengaged and guessed correctly. In these simulations, the correlation between attempts and mastery can be increased by increasing $P(T)$ or decreasing either $P(G)$ or $P(D)$. Similarly changing the parameters in the opposite direction or increasing $P_{unmastered}(T)$ or $P(E)$ can decrease accuracy.

4.4 Features

We train our model to predict wheel-spinning on the later skills, A4 and A5, and automatically suggest interventions in the form of if and which prerequisite to review. In both of the student models, needing a higher number of attempts on an activity is positively correlated with a skill not being learned. With this in mind we use the following three features and corresponding interventions: (1) Activity identity (A4 or A5): If assigned a high contribution, the corresponding intervention could be redesigning the level. (2): Number of attempts on the most recent prerequisite as defined by the prerequisite graph. The corresponding intervention would be to have the student review that activity. (3): Number of attempts on the second most recent prerequisite.

4.5 Results

4.5.1 Evaluation Metrics

To evaluate the accuracy of our method, we consider the frequency with which the method predicts a correct action, which includes correctly deciding to not intervene and correctly suggesting a correct intervention. We refer to student-problem pairs that would lead to wheel-spinning if no intervention is given as a wheel-spinning pair and student-problem pairs that would not wheel spin if no intervention is given as non-wheel-spinning pairs. Across all student-problem pairs, we define four counts:

1. Correct-Pairs_No-Intervention (CP_NI): the number of student-problems where the model correctly suggests no intervention)
2. Correct-Pairs_Intervention (CP_I): model correctly suggests the right intervention

Student Model	n	Method	Accuracy	Precision	Recall	F1	AUC
1	0	XGB	88%	0.68	0.72	0.70	0.89
		LR	86%	0.71	0.50	0.59	0.89
	5	XGB	94%	0.79	0.93	0.85	0.97
2	0	XGB	83%	0.75	0.58	0.65	0.79
		LR	80%	0.75	0.44	0.55	0.79
	5	XGB	93%	0.81	0.99	0.90	0.96

Table 3: Simulation wheel-spinning prediction results averaged over 200 simulations. XGB refers to XGBoost, LR refers to the Logistic Regression baseline. At $n=5$ attempts the performance of XGB and LR are very similar so only the XGB results are included. At $n=0$ attempts, XGB has higher Accuracy and F1 than LR.

3. Missed-Pairs (MP): model either suggests an incorrect intervention or incorrectly does not suggest an intervention)
4. Interrupted-Pairs (IP): model incorrectly suggests giving an intervention when it is unneeded, or suggests the wrong intervention

Note that IP and MP both include students that were wheel-spinning but the model suggests the wrong intervention since such students are both not helped (“missed”) and would be asked to do something not useful (“interrupted”). Additionally, we classify wheel-spinning students who mastered both prerequisites and were still jumped back to a prerequisite as CP_I as insights from our domain expert suggests that jumping back when a student is wheel-spinning and possibly disengaged can be a helpful intervention.

Let S be the total number of student-problem pairs and define *accuracy* as the total percentage of student problem pairs that were given a correct intervention ($= \frac{CP_NI + CP_I}{S}$); *miss rate* as the percentage of wheel-spinning instances that were not identified or which were proposed the incorrect intervention ($= \frac{MP}{CP_I + MS}$), and the *interrupted rate* as the percentage of Interrupted Pairs out of all student-problem pairs that did not need an intervention ($= \frac{IP}{CP_NI + IP}$).

4.5.2 Results

For all results, we averaged over $N=200$ simulations by repeating 200 times the data generation procedure outlined in Sections 4.2.1 and 4.3.1. With this size of N , the standard deviation for all results reported in this section is less than 0.005 (for results reported in percentages, less than 0.5%).

Student Model	n	Method	Accuracy	Miss Rate	Interrupted Rate
1	0	Ours	88%	28%	8%
		LR	86%	50%	5%
	5	Ours	92%	14%	8%
		LR	92%	14%	8%
2	0	Ours	83%	42%	8%
		LR	80%	56%	5%
		FI	75%	68%	16%
	5	Ours	92%	4%	10%
		LR	86%	25%	17%
		FI	84%	34%	19%

Table 4: Simulation intervention suggestion results, averaged over 200 simulations. Ours refer to our proposed method, LR refers to the Logistic Regression baseline, FI refers to the overall XGBoost feature importance baseline. Notice the FI baseline was not included for Student Model 1 because in that simulation, there was only one cause of wheel-spinning (Prerequisite 2) so FI is exactly equivalent to our method.

We report the results of the XGBoost and Logistic Regression (baseline) models for predicting wheel-spinning in Table 3. For lower values of n , XGBoost can achieve higher accuracy and F1 when predicting wheel-spinning. As n increases, the dataset becomes heavily skewed towards data-points with wheel-spinning as well as students needing less than n attempts correctly automatically labelled as no-wheel-spinning, resulting in both methods achieving high accuracy.

We report the results of our method for identifying interventions for both student models in Table 4 when making the prediction at 0 attempts and 5 attempts ($n = 0$ and $n = 5$). The probability threshold of the wheel-spinning model over which we suggest an intervention (p) was set to 0.5 for both. Our approach achieves high accuracy for both student models even when making early predictions before the student begins an activity (0th attempt). Additionally our method is mostly able to do better than the Logistic Regression baseline (LR). For Student Model 1, because there is only one cause of wheel-spinning the prescriptions of the XGBoost Overall Feature Importance Baseline (FI) was exactly the same as our method. However in Student Model 2 where there is more than one cause of wheel-spinning, our method performs much better.

Due to the fact that students are modelled stochastically, we are not able to achieve 100% accuracy as the correlation between number of attempts on a problem and problem mastery is not perfect. However we can increase the accuracy by making the prediction at a later number of attempts as shown in Table 4 when the intervention prediction made at the fifth attempt ($n = 5$). Our accuracy for both student models increases and the miss rate for both decreases. As we increase the attempt number at which we consider providing an intervention, all the student problem pairs that resulted in less than 5 attempts were correctly not intervened upon and automatically categorized as CP_NI. We provide further discussion of this hyperparameter and the p hyperparameter in the Discussion (Section 6).

5. CAN'T WAIT TO LEARN

Our method was motivated by our collaboration with the Can't Wait to Learn (CWTL) program of War Child Holland. CWTL is a tablet based, curriculum aligned, self-paced, autonomous learning program that aims to teach basic numeracy and literacy skills to children in conflict-affected settings who are facing challenges in accessing quality education. The program is delivered on a tablet and targets learning objectives from grade 1-3. Based on the context, the program can be used as a standalone or a supplemental educational program. CWTL is currently rolled out in Sudan, Lebanon, Jordan, Chad, Bangladesh and Uganda. Prior studies found the program was able to result in increased psychological well-being as well as positive learning outcomes in multiple countries [7, 21].

5.1 Game Mechanics

For our application we focus on the English reading program in Uganda where we notice a high amount of wheel-spinning. In classrooms utilizing the program, the instructor to student ratio is large, with class sizes of 114 students per teacher on average. The game takes place in the game world shown in the left panel of Figure 3a. In the game, the student is a member of a Ugandan village and the overarching narrative of the game is to help each village member achieve their goals by playing educational mini-games. The educational mini-games (Figure 3a right panels give two examples) and the instructional videos explaining concepts, such as letters or more complex vowel sounds, form the main educational mechanism. Each educational activity in the program is a specific instance of a mini-game and the curriculum is a fixed linear curriculum of a sequence of these educational activities. For example, in the mini-game at the top right of Figure 3a, the goal concept is learning to combine sounds of words beginning with “o”. In the specific practice question shown of this mini-game, students first tap the blue buttons to listen to the sounds the “o” and “ff” components of the word make separately. To answer the question correctly, they must then tap the correct picture describing the complete word (“off”). To succeed on the activity students must answer 8 out of 10 instances of this question correctly as described by the green the orange circles displayed at the top. Students practice each activity repeatedly until they achieve this success criteria. When a student succeeds at an educational activity they are progressed to the next activity in the curriculum.

5.2 Wheel-Spinning Details

In analyzing the data, we find that 2.4% of student-problem pairs exhibit wheel-spinning. This is lower than in other systems because there exist easier activities for entertainment, engagement, morale, and for gaining initial familiarity with a new concept without too much cognitive overload. Wheel-spinning is still a problem as we find that 51% of students wheel spin at least once. The bottom plot of Figure 3b shows time played compared with the last activity reached. The students who are below the curve whom we would like to help are circled in orange.

To determine the threshold of attempts to define wheel-spinning, we examine plots of student attempts on the game they are currently playing at the end of the most recent log file. If students are stuck on an activity, they are spending more time on it and have a higher probability of being

Figure 3

on that activity when the playing session ends. Therefore the activity the student is currently playing at the time the log file was accessed is correlated with activities students are wheel-spinning on. We compared the distribution of attempts of the problem students are currently on to the distribution of attempts on the activities they played 1 or 5 activities ago, which are less correlated with wheel-spinning. We find a non-negligible percentage of students need 10 or more attempts on the current activity they are playing (27%) while few students require 10 or more attempts on activities played 1 activities (6.8%) or 5 activities (5.9%) ago. We therefore defined wheel-spinning as failing 10 or more attempts on an activity.

5.3 Model

In our model we used the following actionable features and describe the corresponding intervention. We highlight the actionable features that allow for in game interventions in **bold**. These are especially helpful in our domain where student to teacher ratios may be large. We also provide an example of a non-actionable feature¹:

(1) **Last Played**: If there has been a long duration since the student last played, the intervention is to diagnose and have them review what they forgotten. (2) **Number of attempts on the Prerequisite 1, 2 and 3 Prerequisites ago**: A small portion of the prerequisite structure is shown in the top image of Figure 3b. These features use the prerequisite graph to find the last, second to last, and third to last prerequisite in the curriculum. These features in the CWTL domain can be evidence that a student did not master the corresponding prerequisite. The intervention is to have the student practice the prerequisite. (3) **Mini-game Type**: Allows the model to identify if a mini-game should be redesigned. (4) **Number of attempts on the first video**: To pass any video, a student only needs to watch it completely.

¹We also included other non-actionable features to reduce confounding and improve prediction accuracy which we omit in sake of clarity and brevity. Some examples of other non-actionable features included were the number of times mini-game was seen before, the Learning Level, which gives a rough location of where the student is in the curriculum, as well as other features helpful for distinguishing current student location in curriculum.

The number of attempts on the first video can be an indicator of low technological fluency. The intervention is to have a notification that encourages them to ask a teacher or a peer for help. (5) **First Time Mini-game Type Seen?**: Students generally will need more attempts the first time they experience a mini-game. So this feature, while not actionable, allows the model to make more accurate predictions.

5.4 Results

We first examine the accuracy of our model at predicting wheel-spinning. We used data from 1170 students. Students were assigned randomly to the training and test set with 80%, or 943, students assigned to the training set. The students completed 60 activities on average. There were a total of 55,035 student-activity pair datapoints in the training set with 1,294 of them as wheel-spinning (2.4%). There were a total of 15,004 datapoints in the test set with 322 of them as wheel-spinning (2.2%). These datapoints were all used in the $n = 0$ condition. Considering only the student-activity pairs that required 5 or more attempts ($n = 5$), the training set had 2568 datapoints (50% wheel-spinning - there were still 1,294 wheel-spinning datapoints since only datapoints with less than 5 attempts were removed) and the test set had 664 datapoint (48% wheel-spinning). At $n = 9$, the training set had 1454 datapoints (89% wheel-spinning) and the test set had 365 datapoint (88% wheel-spinning).

As shown in Table 5, while our accuracy is quite high, due to the class imbalance, precision, recall, and F1 are low. We tried a variety of different models such as CART decision trees and Random Forests and we found the model we used, XGBoost, to do the best by a slight margin over Random Forests and significantly over CART. We additionally report results for Logistic regression to show that for lower values of n , it is not able to achieve the same accuracy as XGBoost. As with the simulations, as the value of n increases, the accuracy difference of the two models on predicting wheel-spinning decreases as both models achieve high accuracy at higher values of n . This is due both to a higher balance of wheel-spinning datapoints in the dataset and automatically correctly predicting not-wheel-spinning on students who needed less than n attempts. However this increased accuracy at higher values of n is at the expense of allowing some of the students who will eventually wheel-spin

n	Method	Accuracy	Precision	Recall	F1	AUC
0	XGB	93%	0.21	0.60	0.31	0.91
	LR	88%	0.12	0.60	0.19	0.86
5	XGB	98%	0.60	0.60	0.60	0.99
	LR	98%	0.53	0.58	0.55	0.99
9	XGB	99.7%	0.90	1	0.94	0.999
	LR	99.7%	0.88	1	0.94	0.99

Table 5: Wheel-Spinning Prediction: XGB refers to XGBoost, LR refers to the logistic regression baseline. LR has worse predictive accuracy and a lower F1 score than XGB when the prediction is made at lower values of n .

on a problem still spend multiple attempts on the problem. To deploy a system we would work with a domain expert to decide the n that would be best.

To verify the method, we compare our method’s predictions to those an expert would prescribe. To obtain the expert prescription, we blinded the domain expert author of this paper, by showing them the cases and asking for their prescriptions before sharing with them the details or results of the model. To generate the test cases, we randomly sampled true wheel-spinning student-problem pairs of that were also predicted as wheel-spinning by the model. To get diverse cases, sampling was done by throwing out newly sampled cases that were very similar to two or more previously selected cases, until we had 6 cases total. For purposes of making a comparison, we made a list of possible causes and interventions for the domain expert to choose from, including a none-of-the above choice. In our model, some features allow for immediate actions (reviewing a prerequisite problem) while others do not (redesigning an educational activity). The immediately actionable features are much easier to intervene on and based on our expertise gained, are much more favorable to an expert or instructor. To reflect this, we made the decision (before discussing the methods and giving the examples to the expert) to choose the maximum immediately intervenable feature if its Shapley value is greater than half of the maximum feature Shapley value.

The cases are shown in Table 6. The expert’s prescription and the suggestions of various algorithms are shown in Table 7. Overall we found that our method can be promising for automatically suggesting correct interventions. Our method’s suggested interventions agreed with the domain expert’s prescribed interventions 4 out of 6 times, but not in Cases 1 and 6. Additionally our method performed better than logistic regression and the highest overall XGBoost feature importance baselines.

In Case1, the expert believed the exact identity of the educational activity, a feature we did not include was the true cause of the wheel-spinning and the intervention would be to redesign that particular activity. While we did include the mini-game type of each activity, we did not include the unique identity of each activity in the model as it would result in too many features compared to the amount of data we had. Therefore one tradeoff of our method that needs to be made when there is limited data is using as many features as we can to catch all possible causes and using only the most important subset of the features to maintain model robustness. In Case 6, even though the prerequisite struc-

Features	Case1	Case2	Case3	Case 4	Case 5	Case 6
Mini-game (MG)	31	31.	611.	31	31.	546
Last Played (s) (LP)	34.	10.	6	10	12	25
First Time Seen? (F?)	F	F	F	F	F	T
Attempts Prereq1 (P1)	1	1.	1	7	12	\emptyset
Attempts Prereq2 (P2)	1.	1.	1.	1	1.	\emptyset
Attempts Prereq3 (P3)	1.	4.	1.	3	4.	\emptyset

Table 6: The 6 cases from the CWTL dataset used for qualitative evaluation of the methods.

	Expert	Ours	LR	FI
Case1	\emptyset	P3	P3	P3
Case2	P3	P3	P3	P3
Case3	MG	MG	MG	P3
Case4	P1	P1	P3	P3
Case5	P1	P1	P3	P3
Case6	P1	F?	F?	P3
Accuracy	-	4/6	2/6	1/6

Table 7: A comparison of our method and various baselines with the Expert’s prescription. Ours refers to the method described in this work, LR refers to the logistic regression baseline, and FI refers to the XGBoost overall feature importance baseline. MG refers to the “Mini-game” feature, F? refers to “First Time Seen?” feature, P1, P2, and P3, refer to “Attempts Prerequisite1”, “Prerequisite2” and “Prerequisite3” respectively and \emptyset refers to an expert prescription not in the list of what the model can suggest.

ture was created together with the domain expert, during the activity of prescribing interventions, the expert realized there may have been an incorrect dependency in the graph. Where under the original graph there were no prerequisites for this activity, under the new prerequisite graph this activity would have prerequisites. This case highlights the importance of having the correct curriculum graph.

In both the incorrect cases it would not have been feasible for our method to have obtained the correct answer, suggesting the ability of our method to identify correct interventions given correct inputs.

6. DISCUSSION

6.1 Possible Improvements With More Data

The program is currently running and data is being collected. As the amount of data increases and even more expressive function classes, such as neural networks, can be robustly trained, it is possible for the model to become more accurate. Additionally currently we have limited data, especially of the wheel-spinning class, therefore we do not include all possible helpful features, such as exact activity identity, to ensure model robustness. This omission can cause errors such as in Case 1. As more data becomes available this tradeoff between including features and model robustness becomes less important. More features can be included for more accurate intervention predictions.

Table 8: Parameters for Student Model 1

P(T) “easy”	P(T) “hard”	P(G) (A1,A2,A3)	P(G) (A4,A5)	P(S)	“hard” Skill
0.5	0.01	0.01	0.005	0	A2

(a) Sweeping n ($p = 0.5$) with Student Model 2 (b) Sweeping p ($n = 0$) with Student Model 2

6.2 Setting Hyperparameters

As shown in both the results sections, our prediction at the 0th attempt of a student activity pair (before the student starts an activity) can be inaccurate. As we increase the number of attempts, n , before we intervene, we are able to increase accuracy as we by default do not intervene on students who need less than n attempts. However this increased accuracy comes at the expense of letting the students who will wheel spin spend time unproductively attempting the activity. This tradeoff may also not be feasible in environments where students may dropout before n attempts such as educational games played in a casual setting. We illustrate the miss rate decreasing and the accuracy increasing as we increase the number of attempts on which we make the prediction for Student Model 2 (Section 4.3) in Figure 4b. We fix the threshold probability of the wheel-spinning model output to make prediction (p) at 0.5.

Another key design choice touched upon is setting p , the threshold of the wheel-spinning model output for classifying wheel-spinning. To give a concrete example, changing the threshold from the default 0.5 to 0.7 would mean we need the wheel-spinning model to output a probability of 0.7 on a student-activity pair before we decide to suggest an intervention. Therefore at every attempt, we can trade off between correctly suggesting an intervention for a student-question pair and “interrupting” students by changing the certainty threshold. We examine this tradeoff using simulations following Student Model 2 (Section 4.3) at $n = 0$ and plot this in Figure 4b. As expected, as we increase the threshold, the missed rate increases as the interrupted rate decreases.

6.3 Limitation: Does Not Establish Causality

One limitation of this method is causal inferences cannot be made. To illustrate this we consider simulations following the simulation procedure of Student Model 1 (Section 4.2) under a new set of parameters given in Table 8. In this case we make A2 difficult instead of A1. As shown in Figure 2a, A2 only affects A4. Students who struggle due to unmastered prerequisite skills only struggle on A4. There will be very few students who, due to randomness, will struggle on A5. Therefore A4 will be positively correlated with wheel-spinning. However the design of A4 is not the direct cause of most students’ struggling where the true cause is the lack of mastery on A2. Looking into the Shapley values, A4 is chosen incorrectly as the highest valued feature for 11% of all true positive wheel-spinning cases. This can inaccurately lead to an assumption that A4 needs to be redesigned. While redesigning A4 could indeed reduce the number of students wheel-spinning on A4, if students master A2, they will not

struggle more on A4 than they would on A5. Therefore suggesting reviewing A2 instead of redesigning A4 as the most likely intervention candidate would be desired as reviewing A2 is often a much lower overhead intervention than redesigning A4. Coming up with solutions for this issue would be an interesting direction of future work.

7. CONCLUSIONS

In this work we propose a method to automatically suggest interventions for wheel-spinning students. To our knowledge this is one of the first investigations of both designing a wheel-spinning model to suggest immediately actionable interventions as well as using interpretable machine learning methods such as Shapley values in educational technology. We evaluate our method’s ability to suggest useful interventions by investigating the correctness of the suggested intervention in two different simulations and through a qualitative investigation comparing the interventions suggested by our method and the interventions prescribed by the expert. We found our method had high accuracy and was able to choose an accurate intervention for more than 80% of the time in the simulations before the students begin an activity. Additionally in our real world setting our suggestions mostly agreed with the expert prescription and the other cases were due to limitations of the model and errors made in the inputs to the model. Our results suggest our method can help inform interventions and improve educational systems to be more effective and engaging.

ABSTRACT

Network analysis in educational research has primarily relied on self-reported relationships or connections inferred from online learning environments, such as discussion forums. However, a large part of students' social connections through day-to-day on-campus encounters has remained underexplored. The paper examines spatial-temporal student networks using campus WiFi log data throughout a semester, and their relations to the student demographics and academic performance. A tie in the spatial-temporal network was inferred when two individuals connected to the same WiFi access point at the same time intervals at the 'beyond chance' frequency. Our findings revealed that students were more likely to co-locate with the individuals of similar gender, ethnic group identity, family income, and grades. Analysis of homophily over the semester showed that students of the same gender were more likely to co-locate as the semester progressed. However, co-location of the students similar on ethnic minority identity, family income, and grades remained consistent throughout the semester. Mixed-effect regression models demonstrated that features derived from spatial-temporal networks, such as degree, the grade of the most frequently co-located peer, and average grade of five most frequently co-located peers were positively associated with academic performance. This study offers a unique exploration of the potential use of WiFi log data in understanding of student relationships integral to the quality of college experience.

Keywords

Network analysis, homophily, spatial-temporal data, WiFi log data.

1. INTRODUCTION

With massification and globalization of higher education, students are exposed to individuals from a different nationality, ethnicity, gender, and socio-economic background. Universities have long been known as physical spaces where students form lifelong social connections, both for professional social capital and personal networks, such as friendship and marriage [1]. Therefore, understanding how social connections form and change in educational settings, as well as the impact student networks have on learning outcomes, can inform educators of unique ways to improve learners' experience [2].

Educational research offers a range of literatures focused on student networks in both face-to-face and blended or online settings. This paper explores homophily in demographics and academic performance using spatial-temporal student networks" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 194 - 201

settings [2-9]. Social scientists have conventionally derived student networks from self-report surveys [2, 10]. These surveys ask students to list who they are friends with or who they seek advice from [2]. The data can be collected multiple times to track the changes in network formation [10, 11]. Self-reported networks are a source for much of the extant evidence about student networks. However, such data collection is vulnerable to sampling biases (i.e. a low response rate, a sample from one class) where important network observations may be omitted. The timing of surveys may affect derived network features, and frequent surveying of learners can lead to survey fatigue and a lack of responses.

Instead of self-reports, the EDM and LAK communities have based their network studies on the log-data generated from online discussion forums [3, 4, 12-14]. Digital traces from online discussion enabled researchers to capture the structure, frequency, as well as the content of communication exchanges. Student networks constructed from online logs also have limitations. For instance, many online courses do not require that students use online forums. In face-to-face or blended learning settings, students are also less likely to use discussion forums. Therefore, student networks derived from online communication are limited in their generalizability, which remains a major challenge for researchers in this domain.

One underexplored data source for social network research in educational settings is location-based data. Social scientists have long argued that those in close physical proximity are more likely to form a social connection (McPherson, Smith-Lovin and Cook [1], p.430). More recently, relationship between geographic proximity and social ties have been corroborated by fine-grained geo-location-based analysis using mobile technologies. For example, the Copenhagen Networks Study [15] quantified the impact of physical proximity on student network structures using 500 GPS-enabled smart phones. Eagle, Pentland and Lazer [16] also used mobile technologies to compare the network based on physical proximity with the self-report social network and reported that 95% of the network friendships can be accurately inferred from sensor data. Although student location data from GPS and Bluetooth signals has shown to be informative, such methods are expensive to replicate and challenging to scale due to a high equipment cost.

This paper presents yet another source for location-based data to infer student networks. The paper reports on the study of student networks constructed from routinely collected WiFi logs. Such network data is created transparently to the learners as they connect to campus WiFi access points which are ubiquitous across physical campuses. Spatial-temporal ties between users can be inferred based on the overlap of time intervals in which learners connected to the same access point, suggesting a

reasonably close spatial co-location (room level). The study aims to understand the relationship between spatial-temporal ties and student characteristics across time, and predictive potential of the features derived from spatial temporal networks.

1.1 WiFi network data in education research

Wireless local area networks (WLANs) are ubiquitous in higher education as they provide on-campus Internet access to students, teachers, and staff. Despite extensive research using WiFi data, only a limited number of studies has explored their application for educational purposes [17-20]. A common example is the usage of WiFi data to visualize mobility patterns. For example, the iSpots project showed how people move around campus in real-time [17]. Hang, Pytlarz and Neville [20] combined WiFi logs with information about the buildings to extrapolate user preferences, and to predict user locations using graph embeddings. WiFi data has also been used in predictive modelling. Sarkar, Carpenter, Bader-El-Den and Knight [19] estimated the correlations between students' on-campus time based on WiFi logs and academic performance. Zhou, Ma, Zhang, SuiA, Pei and Moscibroda [18] utilized WLAN data to estimate students' punctuality for lectures to assess the lecture's engagement using mobile phone's interactive states at minute-scale granularity.

An application of WiFi data which has yet to be explored in areas such as EDM is the formation of social network among students on campus. In line with previous research on location-based networks [15, 16], social ties between WiFi users can be inferred from spatial and temporal co-occurrences (i.e. two users connected to the same WiFi access point during the same time window). Compared to surveys, discussion forum data, and proximity data collected through mobile devices (e.g. Bluetooth beacons), WiFi data provides a fine-grained alternative that records the dynamic changes in social interactions over a long period of time. Importantly, WiFi logs can capture physical social interactions and can scale at a relatively low cost. This paper presents initial steps towards exploring spatial and temporal information in the analysis related to student learning.

1.2 Research questions

Individuals are likely to share social connections with others similar to them, a phenomenon known as homophily [1, 21]. In educational settings, researchers have observed homophily based on gender [22], ethnicity [23], international/domestic country of origin [10], study major [24], socio-economic status [23], and academic performance [25, 26]. It might be expected that high-performing students seek friendship with other high-performing peers as part of their academic identity [27, 28], or that groups of high performing learners joined by lower performing learners will raise up those learners [29]. While there has been a large literature exploring the homophily effects in educational settings using traditional questionnaires or interactions in online learning environments, there remains a paucity of research that utilizes location-based data for such purposes. We hypothesize that students with similar traits are more likely to spend more time together on campus, i.e. in a spatial temporal co-occurrence from which a social connection can be inferred.

RQ1: How do demographic characteristics and grades affect the likelihood of spatial-temporal co-occurrence among students?

Second, we examine if spatial-temporal student network can capture social selection processes among students, also a phenomenon previously observed in social student networks.

'Social selection' refers to the choice to interact with others of similar status or value, and has been observed in various educational settings [27, 28]. With the increasing availability of digital data in education (i.e. LMS, online discussion forums), researchers are enabled to observe the dynamics of social selection processes with high temporal precision. In these regards, we are interested in understanding the temporal changes in the homophily effects of demographics and academic performance over time. For example, one might expect that at the beginning of the semester, students are more likely to form friendships based on similarity in demographic attributes as they have not acquired sufficient information about their peers' academic ability. One might also expect that as students approach the end of the semester, more social ties will be formed within similar performance groups. This leads us to our second research question:

RQ2: How does homophily based on demographic characteristics and academic performance change over time?

In addition to these questions, previous studies [7, 21, 26] have confirmed a positive relation between the degree of social integration/participation and academic performance. Motivated by this, we are interested in the predictive potential of 'peer effects' for grade performance using location-based network data. The relationship between that of a peer and one's characteristics has been studied for dormmates, as well as classmates, schoolmates, or children from the same neighborhood [29]. Administrative records of class co-enrolment have also been shown to capture this relationship in predictive models [24, 30]. Therefore, it would be reasonable to expect that spatial-temporal student networks can be useful for engineering features based on the peers a student is co-located with.

RQ3: How do network indices of spatial temporal networks relate to student performance?

2. METHODS

2.1 Datasets

Data in this study were collected from 3,915 students enrolled in five large STEM freshman courses at the University of Michigan, USA during the Fall semester of 2018. The selected courses include introductory physics, calculus, biology, chemistry, and psychology. Note that while these make up only a small fraction of all available offerings, they are considered to be foundational for a wide range of degree programs. That is, these courses serve as a gateway into the discipline, account for a significant portion of total credits registered, and are an integral part of one's academic career upon which we can leverage data collection to better understand the broad needs of incoming students and to improve instruction. The format of these courses is primarily didactic in nature, consisting of large lecture-style classes with hundreds of student enrollments. Content coverage is relatively stable between terms albeit with changing instructional teams, and the diverse student body, both in terms of demographics and measures of performance, was a key determinant in selecting these log data to represent students' first-year experience.

All data were de-identified. The dataset contained 91.7 million time-stamped entries recording log data between each device being connected to a particular WiFi access point. Each entry contained a unique user ID, a timestamp, a timestamp when a device was disconnected from a WiFi access point, a WiFi access point descriptor which (often) included a physical location such

as a building name and room number, and the device MAC address (Table 1).

Table 1. De-identified sample WiFi data

ID	Timestamp	Session End	Access point	MAC
A1234	2018-09-24 08:00:00	NA	TWC-1023	XYZ123
A1234	2018-09-24 08:02:00	NA	TWC-2013	XYZ123
B2314	2018-09-24 08:00:03	2018-09-24 08:00:55	BAHR-1210	XYZ125
C2153	2018-09-24 08:00:05	NA	CQTB-3734	XYZ121

The data were pre-processed by dropping all records generated by MAC addresses that were connected to access points within a single building, because they were likely to be stationary devices, such as computers at the libraries or lecture halls. Second, we computed a “connected time” feature for each user by subtracting two consecutive timestamps ($t_2 - t_1$). For example, the connected time for user A1234 to access point TWC-1023 was 2 minutes (Table 1). The connected time feature is important for the subsequent network modeling, which requires a co-located time between any two users. Since the connected time could be biased when a device became disconnected (i.e. students left the building), we removed all data entries which contained a session end’s timestamp. After the pre-processing, we retained 80.9 million records of 3,910 users, and these records were joined with the demographic information and final grades for a semester.

2.2 Analysis

2.2.1 Compute co-located time

To draw inferences about the network structure from WiFi data, we created an undirected weighted one-mode network (i.e. user-user). A tie’s weight equaled to the total amount of co-located time between two users. Figure 1 visualizes the temporal changes in WiFi access points of two users on a particular date from 08:00 to 20:00. These two users spent a large amount of time in the morning at a fixed WiFi access point, possibly attending a lecture. In the afternoon, these two users shared the same access points for 2 hours. After that, each user went on about their day to different areas on campus.

Figure 1: Temporal changes in WiFi access points of two users throughout a day. The boxed area indicates a two-hour period where these users shared the same access point

The co-located time between each pair of users was computed using the *roverlaps* package and stored in a 3910 x 3910 adjacency matrix.

2.2.2 Exponential random graph models (ERGMs)

RQ1 seeks to understand how demographic characteristics (e.g. gender, ethnicity, minority, under-representative, family income, parents’ educational level), and academic performance relate to the formation of ties amongst students. Specifically, we model if students from the same background or having the same academic performance were more likely to form a connection. We used Exponential Random Graph Model (ERGM) techniques which have been used to explore homophily in network formation in

educational data previously [9, 13, 14]. ERGM, also known as a p^* model, is a stochastic model that specifies the probability of the entire network as a function of its network properties [31].

$$P(Y = y) = \exp(\theta'g(y)) / k(\theta)$$

- Y is the network realization;
- y is the observed network;
- $g(y)$ is a vector of model statistics for network y ;
- θ is the vector of coefficients for those statistics, and
- $k(\theta)$ represents a normalizing factor, calculated as the sum of $\exp(\theta'g(y))$ over all possible networks.

This can be expressed as the conditional log-odds of a single tie between two actors i and j :

$$\text{logit}(Y_{ij} = 1|y_{ijc}) = \theta'\delta(y_{ij})$$

where θ is the coefficient and $\delta(y_{ij})$ is a change statistic.

To translate this into our context, ERGM was used to estimate the likelihood, expressed in conditional log-odds of two students being connected, given the similarity in their demographic characteristics and course grades. Model fit was examined with AIC and BIC (the lower the better model fit) and visual plots.

An important analytical decision was taken when weighted ties in our spatial temporal network were transformed into binary relations. To do so, we applied a filtering technique called dyadic thresholding. That is, a tie between two students would be kept when its weight was more than two standard deviations above the mean of all weights across all students. In other words, two users were considered to have a social connection when they spent a large proportion of their time on campus around each other.

To address RQ2, we applied a time window slicing technique to create separate ERGMs for a network that captured every month of activities from September to December. We then compared the changes in network homophily based on demographics and academic performance across four months.

Finally, for RQ3, network indices at the level of a node/student were incorporated in mixed-effect regression models. The models predicted grades as a function of demographics and network properties. To test the relationship between peer performance and predicted grade, we incorporated two features: 1) the average grade of the most frequently co-located peer, and 2) the average grade of five most frequently co-located peers into the model.

All the analyses were carried in R 3.6.2. ERGMs were fit using the *statnet* package [31, 32], mixed-effect regression models were run with the *lme4* package [33]. A simulated dataset and the code will be made available on Github.

(https://github.com/quan3010/EDM20_Nguyen).

3. RESULTS

3.1 Network description

The data for network construction was comprised of 80.9 million log events of 3,910 users over four months. From that, we derived a weighted, undirected network with over 6.54 million weighted ties. An average co-located time between two students was 0.98 hours, with a standard deviation of 12.37 hours. This weighted graph was converted into an unweighted graph network by setting a cut-off value equal to two standard deviations about the mean, i.e. 25.74 hours. Thus, in the modelled network two users shared a tie only if they spent at least 25.74 hours together over a four-month period. The final network had 3,910 users and a total of

18,704 ties. In such a network, the median number of ties was 8 with maximum of 63 ties. For 50% of the students the range of connections was from a minimum of 3 peers to a maximum of 14. The average co-located time between two users was 120 hours, with a minimum of 25.74 hours, median of 38 hours, and a maximum of 1397.62 hours.

NA	20	0.5%
----	----	------

Table 2 provides descriptive statistics for 3,910 students in this study. There was a rough balance in the number of female and male students. This is important since homophily can occur at random, for instance when a relative size of a subgroup is markedly different. White was the most frequent ethnicity, followed by Asian and Hispanic. A third of the sample identifies as an ethnic minority and 16.1% was categorized as under-represented minority. The family income distribute are right-skewed with over a quarter of students report household income of over \$200,000¹. Academic performance in this semester followed a bimodal distribution with of the majority of students performed at the A-range and B-range.

3.2 Homophily based on demographics and grades

Table 3 reports the results of three ERGM models. Model 1 serves as the baseline model, which accounts for the density of the network. The log-odds of a tie was -6.01 which translates to a probability of a tie exists equal to 0.24% (i.e. 18,704 ties divided by a total of 7.64 million possible ties).

In model 2, we added five nodal attributes, including gender, ethnicity, ethnic minority status, under-represented minority status, and family income, to explore homophily related to demographics. Our results showed that students from the same gender were more likely to form a tie than those with different gender, with the probability of a same-gender tie being 62%. Ethnicity and underrepresented minority status of the student did not have any statistically significant effect on the formation of network ties. This may be explained by the effect of the minority variable, which already accounted for ethnicity and unrepresented groups. Although a social connection was more likely to exist between students from the same minority group (i.e. non-minority, international, minority), the effect was marginal with a probability of only 54%. Family income also had a small effect on the formation of ties. The probability of ties to exist between two users with the same family income was 53%.

Table 3. Homophily effects of demographics and grades

	Model 1	Model 2	Model 3
ties	-6.010*** (0.007)	-6.375*** (0.016)	-6.444*** (0.017)
gender		0.479*** (0.015)	0.479*** (0.015)
ethnic		-0.006 (0.022)	-0.008 (0.022)
minority		0.157*** (0.021)	0.161*** (0.021)
underrep		0.004 (0.018)	-0.004 (0.018)
family_income		0.135*** (0.021)	0.132*** (0.021)

AIC	262,286	261,101	260,913
BIC	262,300	261,184	261,010

Note: * $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$

Coefficients calculated in log-odds, standard errors in brackets. Finally, in model 3, we added student's grades to examine homophily related to academic performance. The probability of a tie among same-grade students was 55%. To conclude, we observed a strong homophily network effect in gender, and marginal effects in minority identity, family income, and academic performance. Spatial-temporal networks also captured the commonly observed patterns of social homophily. This suggests that spatial-temporal networks reflected the social connections underpinning the co-location patterns.

The measures of homophily based on demographics have important implications to the understanding of diversity and inclusivity in higher education. The mere presence of structural diversity in student body (i.e. the proportional representation of groups of students from different backgrounds) does not guarantee the interactions between these diverse groups (Puritty et al., 2017). Homophily measures could serve as an indicator of how diverse and inclusive the social interactions between students are. A highly homophilous network could signal social segregation, and to some extent, inequality in student body as students are less likely to form a connection with peers who are demographically different than themselves. The use of WiFi data could support the design of physical spaces/educational activities that increase the likelihood of spatial co-occurrences between diverse groups of students.

However, we are careful to draw inferences as to what the homophily represents. Our models do not control for types of building, or events that take place on campus. It is plausible that spatial temporal networks capture both the networks formed based on foci of activity (classes, living arrangements, cafeteria visits for students with similar schedules) as well as social ties. For instance, gender homophily could be explained by the majority of freshman students sharing their living space with same-gender peers in a residential building on campus. In this case, co-located time between roommates and dormmates would be the highest among freshmen. We did not find any evidence of homophily between different ethnicities per se. However, we observed homophily between different ethnic identities, such as ethnic minority (i.e. Black, Asian, Mixed, Hispanic), ethnic non-minority (i.e. White), and international (i.e. mostly Asian). In other words, there was evidence for inter-ethnic co-location within ethnic minorities.

As can be seen in the model, the addition of the terms decreased the AIC/BIC suggesting improved model fit. We did not manage to fit any of the conventional closure terms, such as popularity (e.g. geometrically weighted degree distribution) or transitivity (e.g. geometrically weighted edgewise shared partners), into the model. Visual examination of the goodness of fit suggested that the model was fit in predicting dyadic-level observations but was limited in reproducing the network structure. These results suggest that the model either requires to add control variables about the events/reasons for co-location (e.g. lectures, Thanksgiving breaks, exam periods), or that the networks need to be separated to have a more elaborate operationalization of co-location (e.g. residential building, libraries, classrooms).

3.3 Temporal changes in social networks

To examine the changes in the homophily over time, we ran the ERGM model with the same specification for a network capturing co-location in each month (Sep, Oct, Nov, Dec). The coefficients of each model were visualized in Figure 2.

Figure 2. Temporal changes in homophily effects of demographics and grades on network formation (* $p < 0.01$)

We can observe an increasing trend in homophily based on gender over time. The probability of a same-gender tie increased from 61% in September to 69% in December. There was a small increase in the homophily based on grade in October and November but it then decreased in December. The homophily effect of minority identity and family income remained constant over time.

One potential explanation for the increasing trend in gender-based homophily is that students started expanding their social circle with people in the same dorm hall/residential building, who are likely to have the same gender. This could also be explained by the participation in fraternity and sorority activities for freshman. As a result, we observed an increase in same-gender co-location over time as students formed new connections within a fraternity and sorority. Finally, previous studies [29, 30] also observed the intersectional nature of grade-based performance, i.e. high-performing boys are likely to form ties with high performing boys, and the same applies to girls. The consistent trend in performance-based homophily could be explained by the fact that this is the first semester and not only are students new to the institution, but university academic performance was generally not available until the end of the semester. Results suggest that it could be interesting to examine the temporal changes in performance-based homophily over a longer time period, especially in sophomore and senior students.

This finding has important implication to the research of social interactions between students. More often than not, social relations in educational research are collapsed under a static and dichotomous category (e.g. yes/no). In reality, the formation of social relations is a highly dynamic and time-variant process. For example, students could become closer with certain peers while more distant with others as time goes by. Students' social circle could be more elastic during their freshman year but gradually form a close-knit group as they approach their senior year. The networks inferred from WiFi data allow us to explore many questions about the evolution in social interactions between students over time, which could not previously be answered with self-report social network surveys.

3.4 Predicting academic performance

We applied mixed-effect regression models to control for the heterogeneity between courses (Table 4). Grade letters were converted into numeric format as per institutional guidelines, with a maximum value of 4.0. Our findings indicated that in the courses we studied, male students on average achieved 0.08 grade

points higher than female students. Compared to students with a family annual income over \$200,000, which accounted for a quarter of our dataset, students with a family income of \$75,000, \$50,000, and \$25,000 had 0.13, 0.30, and 0.43 grade points lower respectively. The effect of family income became marginal and non-statistically significant once it is above \$100,000. Students from an under-represented minority (i.e. Black, Hispanic, and Native American) also had on average 0.30 grade points lower than a non-underrepresented minority (i.e. Asian, Mixed, and White).

All three network indices had a positive and statistically significant relation with academic performance. On average, each additional tie increased a student's final course grade by 0.014 grade points. For each grade point increase in the most frequently co-located peer, the student's grade increased by 0.07 grade points. For each additional point increase in the average grade of the five most frequently co-located peers, a student's grade increased by 0.15 grade points. It is important to note that our results so not imply a causal relationship. The finding could be explained by a homophily effect (i.e. students co-located with similarly performed peers) or a roommate effect (i.e. performances of co-located peers influence a student's performance).

4. CONCLUSION

This paper explores the use of WiFi data of 3,910 students in Fall 2018 in understanding student physical on-campus connections. Specifically, we explore if spatial-temporal student networks reflect homophily based on demographics and academic performance expected in social networks. Network connections were inferred when two users exhibited a high level of co-located time (i.e. connecting to the same WiFi access point in the same time window). We found evidence of homophily with regards to gender, ethnic minority identity, family income, and academic performance. Gender-based homophily is particularly interesting, given that the composition of the student body has equal share of both genders and that this homophily increased significantly over time. This suggests that observed homophily is not baseline, but largely structural. That is, the organization of physical space, as well as curricular and extracurricular activities may create opportunities for gender-based homophily on campus. Exploring this further may be useful in understanding the effect of various institutional (e.g. gender-based meetups, structured study sessions, or mentoring workshops) and non-institutional (e.g. gender-based social activities, such as fraternity and sorority functions and enrollments) activities on the development of friend and support networks.

In addition, we found that the number of ties and the average performance of the most frequently co-located peer(s) were predictive of academic performance. This is in line with extant literature on self-reported peer effects [29], or the effects of peers observed from academic records [24]. Contextualizing this relationship and determining signals for specific causal activities is a clear next step.

From a theoretical perspective, our results confirmed homophily with regards to demographics and academic performance. At the same time, we extended the findings to capture the temporal changes in homophily within a semester. Our findings suggest that the tendency to form (co-located) connections may vary over time and more longitudinal studies are needed to understand the mechanism behind dynamic homophily.

From a methodological perspective, we demonstrated a novel application of spatial-temporal data in the study of student social networks, which have primarily relied on self-reports and log-data from discussion forums. This opens up a new venue to capture social interactions between students on campus on a large

scale and with fine-grained granularity. Importantly, this can be achieved without the need to collect additional data beyond what has been already collected by the university wireless networks. Location data inferred from WiFi access points can be considered as less invasive than using mobile phone's GPS or location-sensors to track users' location [15, 16]. Future research could combine self-report, discussion forum data, and location-based data to form a more holistic picture of student social networks and to triangulate findings from multiple data sources.

From a practical perspective, this study highlighted several factors that determine the formation of network among college students as well as their effect on academic performance. Such results may be useful to institutions in designing or evaluating location-based initiatives to promote gender, ethnicity, and culture diversity and inclusivity on campus, as well as to support ethnic minority, underrepresented minority in social integration during their time in college. There are opportunities to better understand the impacts of learning communities (e.g. themed residences for groups of students, such as Women in STEM communities), of co-curricular activities and their placement on campus (e.g. guest speakers or academic support groups), and even architectural planning (e.g. the relationship between dormitories and classrooms or libraries) through these methods.

4.1 Limitations

The data used does not capture the use of non-university run network (e.g. cellular networks), when students choose to go offline (e.g. intentionally by powering down their phone or due to low battery), or in spaces on campus without access to university network. There is also an inherent messiness which comes with the use of multiple or shared devices, the former of which is very common and increasing with the use of wearables. Network inference based on co-located time is further biased when students co-locate by random chance or by sharing common activities (i.e. attending lectures, going to the libraries, going to the gym) but do not interact with one another. Similarly, it is possible for students to be in completely different rooms yet connected to the same access point depending upon the wireless network and building topologies, introducing further noise to social network models. As a result, there might be hidden bias when using networks inferred from location data for predictive purposes. More sophisticated network inference techniques may be helpful in understanding this, such as weight/tie reshufflings or spatial/temporal simulations [34], and better cataloging of network endpoints (e.g. classroom, office, hallway) may be helpful in modeling social network relationships.

Finally, the modeling techniques used with the limited dataset chosen required significant computing power. More fine-grained temporal analyses (e.g. weekly or daily models), a longer time frame (e.g. a full academic year or throughout the students' academic career), and increased data (e.g. from more courses and non-freshman students) will only increase the need for computational power.

4.2 Concerns with the Use of Wi-Fi Data

WiFi data is highly sensitive data and the security of the collection, storage, and analysis of such data is of utmost importance. As is appropriate, we sought IRB oversight of our use of this data and worked with institutional data governance teams to ensure the data we received was appropriately stored, was de-identified, and was as minimal as possible to support our analyses.

At the same time, we feel it incumbent upon us to note that research access to such data is under threat by the potential misuse of educational location data for non-research purposes, which does not have to undergo IRB review. Specifically, some have begun to incorporate location data into formative evaluation of students. Location data is captured not only through WiFi, but also Bluetooth beacons and student mobile application software (which may be required), and has been used in an identifiable way to assign students grades based on location (attendance in class) [35]. While there are broad discussions of agency, privacy, paternalism, and ethics which the authors have positions on, the purpose of this section of the paper is to raise the importance such data has in understanding teaching and learning, and to encourage researchers in the field of Educational Data Mining (EDM) to voice opinions on the value of de-identified location data and its use in educational research.

5. ACKNOWLEDGMENTS

This work was funded under the Holistic Modeling of Education (HOME) project funded by the Michigan Institute for Data Science (MIDAS). We would also like to thank the UM's ITS team for their support with data access.

The effect of teachers reassigning students to new Cognitive Tutor sections

ABSTRACT

The design of the Cognitive Tutor Algebra I (CTA1) intelligent tutoring system assumes that students work through sections of material following a pre-specified order, and only move on from one section to the next after mastering the first section's skills. However, the software gives teachers the flexibility to override that structure, by reassigning students to different sections of the curriculum. Which students get reassigned? Does reassignment hurt student learning? Does it help? This paper used data from the treatment arm of a large effectiveness study of the CTA1 curriculum to estimate the effects of reassignment on students' scores on an Algebra I posttest. Since reassignment is not randomized, we used a multilevel propensity score matching design, along with assessments of sensitivity to bias from unmeasured confounding, to estimate the effects of reassignment. We found that reassignment reduces posttest scores by roughly 0.2 standard deviations—about the same as the overall CTA1 treatment effect—that unmeasured confounding is unlikely to completely explain this observed effect, and that the effect of reassignment may vary widely between classrooms.

1. INTRODUCTION

Two closely related pillars of intelligent tutoring systems are sequencing and mastery learning. It has long been obvious that the sequence in which students learn different topics is an important component of a curriculum, due to prerequisites—for instance, students must master arithmetic in order to learn how to solve algebraic equations. A related example is scaffolding, in which learners gradually achieve independence over a sequence of problems; scaffolding “consists essentially of the adult ‘controlling’ those elements of the task that are initially beyond the learner’s capacity, thus permitting him to concentrate upon and complete only those elements that are within his range of competence” [33]. However, measuring the effects of sequencing [21] [9] and determining prerequisites or optimal sequences [29] [31] [17] remains an active area of research.

By “mastery learning,” we mean the idea that students should “progress through topics as they master them,” [22] as opposed to at a fixed pace. This typically results in students within the same classroom working on different parts of a curriculum at the same time.

The Cognitive Tutor Algebra I (CTA1) system [8] includes both features. A particular Algebra I curriculum is programmed into the software, so that students, if left alone, will encounter topics in a specific, intentional sequence. Mastery learning governs how they progress from one section to the next: an underlying knowledge tracing model estimates the probability students have mastered a set of pre-defined skills as they work through problems that incorporate those skills. Students ideally progress from one section to the next only after demonstrating mastery on the previous section's skills.

Mastery learning does not always proceed this way in the CTA1 software. After a student has worked a certain, pre-specified number of problems in a particular section, he or she is automatically promoted to the next section, even if he or she has not mastered its skills [28]. Teachers can also reassign students working on one section to work on an entirely different section. If a teacher reassigns a student to a section other than the next one in the sequence, reassignment violates the intended sequencing as well as mastery learning.

There are a number of reasons teachers may want to meddle in the automatic progress of students through a curriculum [16]. If a teacher observes an advanced student spending time on basic skills, the teacher may move the student to more advanced sections. If certain skills will be on a standardized test, and a teacher wants all students to have had exposure to those skills before the test, the teacher may reassign all of his or her students to work on a section covering those skills. If a teacher notices a student falling behind his or her peers in the classroom, the teacher may choose to reassign the student to the section that the rest of the class is working on, even if the student has not demonstrated mastery on prerequisite skills (at least, within the tutor). If a teacher disagrees with the method a certain CTA1 section employs in teaching an Algebra topic, the teacher may reassign students out of that section, perhaps to the next unit or section in the curriculum.

It is unclear whether reassignment benefits students. On the

Adam Sales and John Pane "The effect of teachers reassigning students to new Cognitive Tutor sections" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 202 - 211

one hand, it violates the design principles of the software. On the other hand, it allows teachers flexibility to teach the material as they see fit, and use the tutor to meet the particular needs of their classrooms.

This paper uses data from a large randomized trial of the CTA1 curriculum to estimate the effect of reassignment. Unfortunately for our purposes, reassignment itself was not randomized—the study was designed to estimate CTA1’s effectiveness, so access to the tutor was randomized instead. Still, log data from study participants includes data on how often each student was reassigned from one section to another, and posttests measure their algebra skills at the end of the study. For those reasons, this data provides a rare opportunity to measure the effect of reassignment, and, by extension, the (joint) importance of topic sequencing and mastery learning.

The following section gives background on the effectiveness trial and describes the data we will use for the study. Section 3 describes propensity score matching, the method we employ. Section 4 describes the propensity score models, which in turn describe characteristics of students who are reassigned. Section 5 describes the matching algorithm and covariate balance. Section 6 gives our main results on the effects of reassignment, including sensitivity analysis to confounding from unmeasured covariates and between-classroom effect heterogeneity. Section 7 concludes.

2. DATA: THE RAND CTA1 EFFECTIVENESS STUDY

In the years 2007–2010, the RAND Corporation conducted a randomized study to test the effectiveness of the CTA1 curriculum relative to business as usual. The study tested CTA1 under authentic, natural conditions—that is, oversight and support of CTA1’s use was the same as it would have been outside of an RCT. The study population consisted of over 25,000 students in 73 high schools and 74 middle schools located in 52 diverse school districts in seven states. Students in Algebra I classrooms in participating schools took an algebra I pretest and a posttest, both from the CTB/McGraw-Hill Acuity series. The pretest was the Algebra Readiness Exam, a 40-item multiple-choice exam testing students’ algebra I prerequisite skills. The posttest was the Algebra Proficiency Exam, a 32-item multiple-choice exam testing algebra I skills including solving equations for an unknown, graphing linear and quadratic functions, calculating complex algebraic expressions and other skills. Data from both exams were scored with a three-parameter item response theory (IRT) model.

Results [19] were reported separately for middle and high schools, in the first and second years of implementation. In the first year, estimated effects were close to zero in middle schools and slightly negative in high schools, with confidence intervals including negative, null, and positive effects in both cases. In the second year, estimated effects were positive—roughly one fifth of a standard deviation—in both middle and high schools, and were statistically significant in high schools. In the high school sample, the difference between the effects in the first and second years was statistically significant as well.

Table 1: The number and percent of students in each study year of the dataset who were never reassigned, or reassigned once, twice, three times, or four or more times

year		# Reassignments				
		0	1	2	3	4+
1	n	1621	552	133	43	34
	%	68	23	6	2	1
2	n	1056	297	193	95	194
	%	58	16	11	5	11

As part of the study, RAND collected basic demographic data from students, including gender, race/ethnicity, prior standardized test scores, and special education, free or reduced-price lunch, and English language learner status.

Carnegie Learning collected computer log data from most users in the treatment arm of the study. At the problem level, this dataset records which problems students attempted, along with timestamps and the numbers of hints and errors for each attempted problem. The dataset also contains data on which sections of CTA1 students attempted, and the result: whether the student mastered the section, was promoted automatically without mastery, was reassigned by the teacher to a new section, or stopped using the tutor altogether midway through the section.

The current study analyzes data from the high school treatment group only, assessing the effect of teachers reassigning students from one CTA1 section to another. Since students in the control arm of the study did not have access to the tutor, section reassignment is not relevant for them. We focus on high school, as opposed to middle school, since the characteristics of Algebra I students tend to differ between the two levels: 8th-grade students only take Algebra I if they are sufficiently advanced, whereas most 9th grade students (who have not taken it already) take Algebra I regardless. Thus, the high school sample was not only larger but also more broadly representative than middle school sample.

Unfortunately, log data was not available for every student in the treatment arm of the study, primarily for two reasons: some students in CTA1 schools nevertheless did not use the tutor, and some students used the tutor but their log data was irretrievable or could not be reliably linked to posttest scores and covariates. This study omitted schools in which data was missing for over 20% of students in either year, leaving 18 schools. Among the students at these schools, we omitted 164 who had no log data, and 242 who worked—but did not complete—only one section or who had no section completion data for some other reason. A total of 4,218 students in 282 classrooms remained in the analysis sample, roughly 70% of the full treatment group.

Table 1 shows the number of included students in each year of the experiment who were reassigned zero, one, two, three, or four or more times. Since the sample size decreases quickly with the number of reassignments, and for the sake of simplicity, we chose to dichotomize reassignment, esti-

inating the effect of being reassigned at least once versus never.

3. STATISTICAL APPROACH

For subjects $i = 1, \dots, N$ in the treatment arm of the CTA1 trial, let Y_i denote subject i 's posttest score, and let $Z_i \in \{0, 1\}$ indicate whether i was ever reassigned. Following [18] and [25], let y_i^0 and y_i^1 denote i 's posttest score were $Z_i = 0$ or 1—i.e., had i not been reassigned, or had i been reassigned, perhaps counterfactually—and let $\tau_i = y_i^1 - y_i^0$ be the effect of reassignment on i 's posttest score. Since y_i^1 and y_i^0 are never simultaneously observed, τ_i is unidentified; however, weighted average treatment effects of the form $\tau^w = \sum_i w_i \tau_i$, with $w_i \geq 0$ and $\sum_i w_i = 1$ may be identified under the right causal assumptions. For instance, had Z been randomized, the average treatment effect, τ^w with $w_i = 1/N$, could be estimated without bias by the difference in the mean of Y between subjects with $Z = 1$ and with $Z = 0$. Of course, reassignment Z was not random, so identifying average treatment effects requires some combination of control for observed covariates and assumptions about unobserved covariates.

Let \mathbf{x}_i denote a vector of covariates for subject i . These include pretest scores, special education, gifted, and English language learner (ELL) status, race/ethnicity (white, black, Latinx¹), received free or reduced-price lunch (FRL). Let $Class_i$ be i 's classroom; since reassignment occurred within classrooms, $Class$ is a covariate as well. If reassignment were randomly assigned, the (theoretical) distribution of \mathbf{x} and $Class$ would be equal between reassigned and not-reassigned students— \mathbf{x} and $Class$ would be balanced. Our strategy will be to construct a randomization scheme in which \mathbf{x} , and, to the extent possible, $Class$ are balanced, and conduct inference under that randomization scheme.

Specifically, we use propensity score matching [23] [27]. The propensity score for subject i , $e_i(\mathbf{x}_i, Class_i) = Pr(Z_i = 1 | \mathbf{x}_i, Class_i)$ is the probability of i being reassigned conditional on covariates \mathbf{x} and classroom. [24] showed that under two conditions, described below, estimates of the average treatment effect conditional on $e(\mathbf{x}, Class)$ are unbiased. To estimate effects, we first estimate propensity scores (Section 4), then identify groups of reassigned and not-reassigned students with similar estimated propensity scores—a “match”—and verify that covariates are sufficiently balanced within the matched sample (Section 5), and, finally, estimate effects within the matched sample 6.

The first condition for propensity score matching is that there is some randomness in the treatment assignment:

$$0 < e_i(\mathbf{x}_i, Class_i) < 1 \text{ for all } i. \quad (1)$$

When (1) fails for a subset of the analysis sample, common practice is to drop that subset and estimate average effects for the remainder of the analysis sample, i.e. the subset for which (1) holds; this subset is referred to as the “region of

¹For the sake of parsimony, these categories were collapsed from a larger set in the original dataset, so that 8 American Indian/Alaskan Native students were categorized as Latinx, 23 Asian/Pacific Islander students and 118 students with missing data were categorized as white, and 22 Other/Multiracial students were categorized as black.

common support” [4] [30]. In this study, including *Class* among the covariates leads to violations of (1). Of the 282 classrooms over the two years of the study, 95 contained no reassigned students, and in 52 classrooms every student was reassigned at least once. In this subset of the data, including 44% of students, $Pr(Z = 1 | Class) = 0$ or 1. Our solution is to drop classrooms in which no one or everyone was reassigned, and only estimate effects for students in classrooms with some reassignment variance, a student-level analysis.

We attempted a parallel classroom-level analysis, in which we matched classrooms in which all students were reassigned to classrooms in which no one was. However, we were unable to construct a match with adequate covariate balance (there were few no-reassigned classrooms with similar mean pretest scores to the all-reassigned classrooms that were of similar sizes). For that reason, we dropped the classroom-level analysis.

The second condition for propensity score matching is that there are no unmeasured confounders:

$$(y^1, y^0) \perp\!\!\!\perp Z | \mathbf{x}, Class \quad (2)$$

Assumption (2) is well known as the Achilles heel of causal inference outside of RCTs. (2) is untestable; its believability depends on what is understood about the process that underlies treatment assignment Z , and what covariates are available for control. In our case, reassignment is poorly understood, and appears highly idiosyncratic [16]. Fortunately, our study includes a pretest measure, and observational studies controlling for pretest scores tend to perform well, and replicate experimental estimates [6] [7]. Section 6.1 discusses a sensitivity analysis that relaxes 2 and assumes reasonable levels of unmeasured confounding.

Our attitude towards propensity score matching is agnostic. If the propensity score models in the following section were approximately correct, and yielded good estimates of the true propensity scores, then the theory underlying propensity score adjustment holds. If not, the process of propensity score matching may still result in a set of matched reassigned and not reassigned students that, on average, resemble each other on all measured covariates. In other words, the (mis)estimated propensity scores \hat{e} may still be approximate “balancing” scores, satisfying

$$\mathbf{x} \perp\!\!\!\perp Z | \hat{e}. \quad (3)$$

Causal inference based on comparisons within these matched sets will still be plausible; indeed, [24] showed that in order to estimate average treatment effects, it is sufficient to condition on a balancing score, rather than the propensity score itself.

Following that logic, we choose propensity score models, and matching schemes based on the fitted models, in order to satisfy (3). Since posttest scores play no role in propensity score estimation and matching, the process may be iterative without affecting the objectivity of the final causal estimate. That is, we may try a series of candidate propensity score models and matches, and choose the one that results in the best covariate balance. Only then do posttests enter the picture, so that we may estimate effects.

All data analysis was done in R [20] using the `tidyverse` suite of packages [32] for data manipulation, plotting, and other tasks. This document was produced dynamically with `knitr` [34]. Source code is available at www.github.com/adamSales/cpEffect.

4. PROPENSITY SCORES: WHO GETS REASSIGNED?

We use multilevel logistic regression [10] to estimate student level propensity scores. The multilevel regression accounts for the nesting of students within classrooms, classrooms within teachers, and teachers within schools. In constructing the model, we give special consideration to the role of pretest scores, a proxy for student mathematical ability at the beginning of the school year, in predicting reassignment. First, we decompose pretest scores into student- and classroom-level components. If w_i is student i 's pretest score, let $w_i = \bar{w}_{j[i]} + \tilde{w}_i$, where $\bar{w}_{j[i]}$ is the average pretest score in i 's classroom $j[i]$, and \tilde{w}_i is the difference between i 's pretest score and the classroom mean. This decomposition was motivated by the possibility that reassignment patterns may differ between high- and low-achieving classrooms, and that a teacher's decision to reassign a student depends on the student's ability relative to the classroom than his or her absolute ability. Second, we modeled the effect of \tilde{w} on Z as linear in the logit scale, but allowed the slope to vary by classroom. This was motivated by the possibility that some teachers use reassignment to help struggling students catch up to their peers, so lower \tilde{w} would predict Z , and other teachers use it to help high-achievers skip sections related to basic skills, so higher \tilde{w} would predict Z . We also considered models incorporating non-linear effects of \tilde{w} , via natural splines [14] but found no evidence that the non-linearity improved the model fit. We fit the model using the `lme4` package in R [1].

All in all, the propensity score model was:

$$\begin{aligned} \text{logit} \{Pr(Z_i = 1 | \mathbf{x}_i, \text{Class}_i = j)\} = & \\ & \beta_{0state[i]} + \beta_1 \tilde{w}_i + \beta_2 \bar{w}_{j[i]} + \\ & \beta_3 \text{Black}_i + \beta_4 \text{Latinx}_i + \beta_5 \text{Male}_i + \\ & \beta_6 \text{Freshman}_i + \beta_7 \text{SpEd}_i + \beta_8 \text{gifted}_i + \\ & \beta_9 \text{ESL}_i + \beta_{10} \text{FRL}_i + \beta_{11} \text{FRLmis}_i + \beta_{12} \text{year}_i + \\ & \gamma_{j[i]} \tilde{w}_i + \epsilon_{j[i]}^{Cls} + \epsilon_{k[i]}^{Teach} + \epsilon_{l[i]}^{Schl} \end{aligned} \quad (4)$$

where $\text{logit}(x) = \log(x/(1-x))$ is the logit function, $\beta_{0state[i]}$ is a (fixed) intercept for each state in the sample, FRLmis_i is an indicator for missing data in *FRL* (which was mode-imputed), and $\text{year}_i = 1, 2$ is the study year for subject i .

Finally, $\gamma_{j[i]}$, $\epsilon_{j[i]}^{Cls}$, $\epsilon_{k[i]}^{Teach}$, and $\epsilon_{l[i]}^{Schl}$ are random effects. The subscripts j , k and l refer to classroom, teacher, and school, respectively; the $[i]$ refers to student, so that $j[i]$ is i 's classroom, $k[i]$ is i 's teacher, and $l[i]$ is i 's school.

$\gamma_{j[i]}$ is a random slope for \tilde{w}_i , varying at the classroom level. This is essentially an interaction term, allowing the slope for (classroom centered) pretest scores to vary from one classroom to the next. However, unlike standard regression interactions, random slopes are modeled as being drawn from a normal distribution, with a standard deviation estimated from the data. This is a form of regularization, shrinking

Figure 1: Estimated coefficients and 95% confidence intervals for student and class-level covariates from model (4).

the classroom-level slopes towards a common value, and allowing stable estimation even with very few observations from each classroom [10] [26]. The set of random slopes γ_j has a mean of zero—the average slope across classrooms is the fixed intercept β_1 . Therefore, the slope for pretest in classroom j is $\beta_1 + \gamma_j$.

ϵ_j^{Cls} , ϵ_k^{Teach} , and ϵ_l^{Schl} are random intercepts for classroom, teacher, and school. These were also modeled as normal with a mean of zero and a standard deviation estimated from the data. Including them in the regression accounts the fact that two students in the same classroom or with the same teacher or in the same school may be more likely to have the same Z —either both be reassigned or neither—than two students in different classrooms, with different teachers, or in different schools.

Figure 1 gives estimated coefficients and 95% confidence intervals for the propensity score model (4). Reassignment was much more prevalent in the second year of implementation than in the first, and classrooms with low average pretest scores reassigned students more often—though the magnitude of this trend is hard to determine, ranging from moderate to very large (the coefficients for \tilde{w} and \bar{w} were scaled by the standard deviations of these variables in the data). Latinx students were reassigned more often than their White classmates.

Students with lower pretest scores were reassigned more frequently than their classmates with higher scores. However, this may vary by classroom. On average, classroom-specific β_{1j} was approximately -0.31 standard deviations, but the 95% confidence interval for the mean includes slightly positive values as well. The standard deviation of β_{1j} , varying by classroom, was estimated as 0.83, suggesting that in some

classrooms the slope on \tilde{w} was moderately positive, and in others it was negative. However, the model was not able to estimate the variance of β_{1j} precisely; the p-value testing the null hypothesis of zero variance was 0.07.² When model (4) was modified so that β_1 was not allowed to vary by classroom, it was estimated as -0.32 ± 0.27 .

5. MATCHING AND COVARIATE BALANCE

We construct a student-level match based on propensity scores on the log-odds scale, i.e. $\log(\hat{e}/(1 - \hat{e}))$. Instead of a pair-matching design, which would necessitate discarding non-reassigned students who would make good matched comparisons, we use a restricted full match design [11]. In this design, the numbers of reassigned and not-reassigned students in each matched set is allowed to vary, so that in some cases several reassigned students may be matched with a single non-reassigned student, and vice-versa. We use the R package `optmatch` [13] to choose the matched sets optimally. The `fullmatch()` routine takes a matrix of discrepancies (e.g. differences in propensity scores) between treatment and control subjects, and arranges them into matched sets so that the sum of absolute discrepancies between matched subjects is minimized.

As described at the end of Section 3, the post-test scores played no role in this process. Hence, we were able to iteratively match students, check covariate balance, modify the propensity score model and/or the matching routine if necessary, and repeat until adequate balance was achieved. Here we present the final match; a record of attempts is available on the first author's github site.

The initial full match based on the log-odds propensity scores yielded decent covariate balance. However, pretest scores were slightly unbalanced, and since we consider pretest to be the most important covariate, we decided to match on the Mahalanobis distances between reassigned and not reassigned students combining propensity scores and pretest scores. Additionally, as displayed in Figure 2, the distributions of propensity scores among reassigned and not-reassigned students do not entirely overlap. Although this is at least partially due to overfitting the propensity score model (4), matching students with highly discrepant propensity scores may hinder the believability of the result. Hence, in our final match we imposed a caliper of 0.3 pooled standard deviations of the Mahalanobis distances. This prevented students with very different pretest scores or propensity scores to be matched. On the other hand, matches were unavailable for 25% of the students in the sample (21% of reassigned students and 28% of not-reassigned students). Propensity scores for these students are colored red in Figure 2. Our effect estimates pertain only to the remaining 75% of students—all in all, 1480 students, 604 reassigned and 876 not reassigned.

Covariate balance after matching was excellent. Figure 3 and Table 2 give covariate balance (standardized differences) before and after matching. They were produced with the RI-

²This hypothesis was tested with a likelihood ratio χ^2 test comparing (4) to a model in which β_1 did not vary by classroom.

Figure 2: Estimated propensity scores for reassigned and not-reassigned students. Scores for students who were excluded from the ultimate match are colored red.

Figure 3: Covariate balance (standardized differences) before and after matching, for student level data. Dotted lines indicate standardized differences of 0.25 and 0.05, following the What Works Clearinghouse standards.

Table 2: Balance (standardized differences) on student level covariates before and after propensity score match. Omnibus p-values testing covariate balance are $p < 0.001$ before matching and $p = 0.95$ after matching.

`tools` package in R [3]. Before matching, several covariates were unbalanced, especially race. Table 2 shows stars reflecting p-values from individual covariate balance tests; nearly all covariates were unbalanced at the $\alpha = 0.1$ level. An omnibus balance test [12] gives $p < 0.001$. Figure 3 shows, as benchmarks, standardized differences of ± 0.25 and 0.5 , corresponding to thresholds given in the What Works Clearinghouse (WWC) handbook³ [5]. Before matching, imbalances in race and FRL missingness exceeded 0.25 , and most other imbalances were greater than 0.05 .

Matching improved nearly all of these imbalances. Most importantly, pretest measures were nearly exactly balanced. None of the individual covariate balance tests was significant at the 10% level or had standardized differences greater than 0.25 , and, with the exception of race, and FRL missingness none of the covariates was imbalanced with a standardized difference greater than 0.05 . The omnibus p-value testing overall balance was 0.95 .

The match also balanced classroom indicators. Before matching, the omnibus p-value testing balance of classroom indicators was < 0.001 ; after matching it was 0.99 .

6. THE EFFECT OF REASSIGNMENT

Table 3 gives five estimates for the effect of reassignment in classrooms where some students, but not all, were reassigned at some point. The first column gives the estimate itself, the second gives the sample size N for that estimate, the third, “Std Error” gives the standard error, and the fourth, “CI,” gives a 95% confidence interval. The last two columns contain sensitivity analyses, described in the following section. All the estimates used a regression routine from the `estimatr` package in R [2], with “HC2” heteroskedasticity-robust standard errors.

The first row, labeled “Raw,” is an unadjusted estimate, comparing all students in the sample who were reassigned to all students who weren’t. There is little difference in their average posttest scores.

The next row, labeled “Matched+Regression,” gives the effect estimate based on the match from Section 5. The lower sample size 1480 reflects the fact that some students were excluded from the match; this estimate only pertains to those who were included. To estimate the effect, we regress posttests on Z including a fixed effects for each match. Let $\hat{\tau}_m$ be the estimated effect in match m . If m is a pair—one reassigned student matched with one non-reassigned student—then $\hat{\tau}_m$ is the difference between the two students’ posttest scores. If there are more than two students in the match, $\hat{\tau}_m$ is difference in posttest means between reassigned and not-reassigned students within matched-set m . If treatment assignment is unconfounded within each match, $Z \perp \{y_C, y_T\} | \text{match}$, then $\hat{\tau}_m$ is unbiased for the average effect of Z on posttest scores in match m . Then the regression estimate is a weighted average of $\hat{\tau}_m$, with weights $w_m \propto (1/n_{1m} + 1/n_{0m})^{-1}$; this weighing scheme minimizes the standard error under standard linear regression assumptions (if the regressions assumptions do not hold, but Z is still unconfounded within the match, then the estimate is still unbiased but the weights are sub-optimal).

The next row, labeled “Match+Regression” uses the same regression model as the “Matched” estimator, but additionally controls for pretest scores (with a natural spline with five degrees of freedom), and indicators for special education status, missing free or reduced-price lunch data, and race. This strategy controls for differences in these covariates left over after the match, accounting for the fact that the match was imperfect.

The “Matched” and “Match+Regression” estimates were almost identical—effect sizes of -0.2 and -0.19 , respectively, with 95% confidence intervals of $[-0.29, -0.12]$ and $[-0.28, -0.11]$. These negative effect estimates suggest that reassignment hurts student learning. The effect size of a fifth of a standard deviation is roughly the same as the overall average effect of CTA1 in high schools in the second year of implementation, as estimated in [19], suggesting that reassignment may negate most of the positive effect of using CTA1.

The next two rows of Table 3, however, suggest that the

³In the context of a randomized experiment with attrition, covariate imbalances with standardized differences greater than 0.25 invalidate a study, whereas differences between 0.05 and 0.25 require statistical adjustment and differences less than 0.05 are acceptable as is.

	Estimate	N	Std. Error	CI	[Pretest]	[State]
Raw	-0.04	1981	0.03	[-0.11,0.03]	[-0.15,0.07]	[-0.16,0.08]
Matched	-0.20	1480	0.04	[-0.29,-0.12]	[-0.35,-0.06]	[-0.36,-0.05]
Match+Regression	-0.19	1480	0.04	[-0.28,-0.11]	[-0.33,-0.05]	[-0.34,-0.04]
Year 1	-0.24	1008	0.06	[-0.34,-0.13]	[-0.42,-0.06]	[-0.43,-0.04]
Year 2	-0.11	472	0.07	[-0.25,0.02]	[-0.33,0.11]	[-0.35,0.12]
Within-Class	-0.17	1981	0.04	[-0.24,-0.10]	[-0.29,-0.05]	[-0.30,-0.04]

Table 3: Estimates of the effect of reassignment without controlling for confounding (“Raw”), controlling for confounding with propensity score matching (“Matched”), with matching and further regression adjustment (“Match+Regression”), overall and separately for each year, and matching by classroom, with further regression adjustment (“Within-Class”). The table gives estimates, standard errors, 95% confidence intervals, and 95% sensitivity intervals assuming an unobserved confounder with properties similar to pretest scores (“[Pretest]”) and to State (“[State]”)

effect of reassignment may depend on context. Each row uses the “Match+Regression” approach, but separately in data from implementation years 1 and 2. It appears that reassignment may have hurt students’ posttest scores more in the first than in the second year of implementation—in the first year, we estimate an effect of -0.24 and in the second year we estimate an effect of -0.11. That said, the difference between the two effects is not itself statistically significant—that is, it may be the result of statistical noise.

The final row of Table 3, labeled “Within-Class,” uses a different confounder control strategy altogether. This estimate matches students by classroom, as if reassignment were randomized within classrooms. To weaken that assumption, the “Within-Class” estimate incorporates additional regression controls: a natural spline with five degrees of freedom for pretest, and indicator variables for the remaining covariates. This strategy estimates a similar negative effect as the others, NA, with a 95% confidence interval of [-0.24,-0.10].

6.1 Unobserved Confounding

The estimates in Table 3 all assumed (2), that there was no unobserved confounding. This assumption is strong, untestable, and could undermine all of the inference in Section 6. For instance, the estimated negative effect may be due to baseline differences in ability, beyond what is captured in pretest scores.

[15] suggest a method of estimating the sensitivity of a regression to an omitted confounder based on benchmarking from observed confounders. Roughly speaking, the idea is to widen the confidence interval from an ostensibly causal linear model to account for the possibility of a hypothetical unmeasured confounder, U , that predicts reassignment and posttests to the same extent as one of the observed covariates. These “sensitivity intervals” account for uncertainty from two sources: random error, and systematic error due to the omission of a confounder.

In order to confound the causal relationship between reassignment and posttests, a confounder would have to predict both. Capturing these two requirements, the method of [15] is based on two sensitivity parameters: first, T_Z encodes the extent to which U predicts Z , after accounting for observed covariates \mathbf{x} . Formally, T_Z is the t -statistic on the U coefficient from an ordinary least squares regression of Z on U and \mathbf{X} . The second parameter is ρ^2 , the squared partial

correlation between posttest scores and U , conditional on \mathbf{x} . Of course, since U is unobserved, neither T_Z nor ρ^2 is known; [15] suggest benchmarking them using observed covariates. That is, imagine each observed covariate, in turn, were unobserved, and calculate its T_Z and ρ^2 given the rest of the observed covariates.

Table 3 includes two such sensitivity intervals. The column labeled “[Pretest]” includes sensitivity intervals for an unobserved confounder that predicts reassignment and posttests as well as do pretest scores—typically the most important confounder. That is, these intervals are 95% confidence intervals that assume the possible existence of an unmeasured covariate as important as pretest. It turns out, in the current analysis, that omitting state indicators would cause more bias than omitting pretest scores; for that reason, the column labeled “[State]” gives sensitivity intervals for an unobserved confounder that predicts reassignment and posttest scores as well as state indicators. Both sets of sensitivity intervals are considerably wider than the corresponding confidence intervals, including both large and small negative effects. Sensitivity intervals for the “Matched”, “Match+Regression”, “Year 1,” and “Within-Class” estimates, whose confidence intervals excluded zero, excluded zero as well. That is, confounding from an unobserved variable as important as pretest or state may have led us to over-estimate the negative effect of reassignment; it may have also led us to under-estimate the effect. However, such confounding cannot explain the sign of the effect we estimated—even assuming the existence of an unobserved confounder as important as our most important covariates, the effect must be negative.

That said, an even stronger confounder, or more complex confounding from several unobserved covariates, may explain the observed results. Without a randomized trial, it is impossible to entirely rule out unobserved confounding.

6.2 Treatment Effect Heterogeneity

Previous research [16] has found evidence for a wide variety of uses for reassignment. In some cases, teachers reassign students who are falling behind their classmates, in other cases teachers reassign nearly the entire class to work on a particular section of the tutor, and in other cases teachers will simultaneously reassign all students working on a particular section *out* of that section. Along similar lines, our (inconclusive) evidence for variance between classrooms in

Figure 4: Classroom-specific effects of reassignment ($\hat{\beta}_1 + \hat{\gamma}_j$) from model (5). Error bars represent standard errors.

the relationship between pretest scores and the probability of a student being reassigned points towards varying uses for reassignment.

If reassignment is used differently from classroom to classroom, it stands to reason that it might have different effects in different classrooms, as well. To test that assumption, we fit a multilevel model with random effects for reassignment, varying by classroom. The model had the same fixed effects as model underlying the “Match+Regression” results described above, as well as random intercepts for classroom and random slopes for reassignment, varying by classroom. Formally, the model is:

$$\begin{aligned} Posttest_i = & \beta_{0,m[i]} + \beta_1 Z_i + \beta_2 SpEd_i + \\ & \beta_3 frlMIS_i + \beta_4 Black_i + \beta_5 Hisp_i + \\ & ns^5(pretest_i, \alpha) + \gamma_{j[i]} Z_i + \epsilon_{j[i]}^{Cls} + \epsilon_i^{Ind} \end{aligned} \quad (5)$$

where $\beta_{0,m[i]}$ is a fixed intercept for each match, $ns^5(pretest_i, \alpha)$ is a natural spline for pretest, with five degrees of freedom and coefficient vector α , and $\gamma_{j[i]}$, $\epsilon_{j[i]}^{Cls}$, and ϵ_i^{Ind} are random effects, modeled as normal with mean zero and standard deviation estimated from the data. Symbols α , β , γ , and ϵ do not represent the same quantities as in equation (4). $\gamma_{j[i]}$ is the random slope for reassignment, varying by classroom; the effect of reassignment in classroom j is estimated as $\hat{\beta}_1 + \hat{\gamma}_j$. That is, $\hat{\beta}_1$ represents the effect of reassignment, averaged over all classrooms, and γ_j represents the difference between classroom j ’s effect and the average. While precisely estimating the effect of reassignment in any particular classroom is beyond the scope of our data, this model allows us to estimate the variance across those effects, as the variance of γ_j s.

The results are displayed in Figure 4. The effect of reassignment in an average classroom is estimated as similar to the effects in Table 3. This effect varies with a standard deviation of approximately 0.25. To test for between-classroom variance, we compared the fit of the multilevel model to an analogous model without random slopes, with a likelihood ratio χ^2 test; the p-value was 0.004. This standard deviation is large enough to imply that the effect will be positive in some classrooms—indeed, Figure 4 shows a number of classrooms with positive effects. That said, the confidence intervals (based on estimates for the conditional variance of random slopes, combined with the standard error of the main effect of reassignment) are all rather wide and nearly all contain zero.

Therefore, while the effect of reassignment was negative, on average, it may have been positive in some classrooms.

This variation could be due to a number of factors, including differences in the composition of classrooms and in when or how reassignment is used. We considered two simple hypotheses about classroom-level predictors of heterogeneous treatment effects. The first hypothesis was that variance in students’ pretest scores within a classroom predicts the effect of reassignment in that classroom. The idea is that some teachers may use reassignment as a tool to address varying student ability—for instance, they may reassign lagging students to help them keep up with their classmates. Classrooms with higher variance in pretest scores afford more opportunities for teachers to use this reassignment strategy. If the strategy is widely used, and either particularly effective or ineffective at boosting students’ posttest scores, there will be a correlation between classroom-level variance in pretest scores and the effect of reassignment.

Our second hypothesis was that the proportion of students in a classroom who have been reassigned may predict classroom-level effects. The idea here is that in classrooms with a low proportion of students reassigned, teachers use reassignment in a more targeted fashion, so it may be more beneficial.

Figure 5 plots random effects $\hat{\gamma}_j$ from model (5) as a function of classroom level pretest variance and the proportion of students reassigned, respectively, with simple OLS fits. A positive relationship between pretest variance and $\hat{\gamma}_j$, and a negative relationship between proportion reassigned and $\hat{\gamma}_j$ are apparent, but with wide standard errors. To test these hypotheses more formally, we re-fit model (5), adding fixed effects for the variance in pretest scores and proportion reassigned, as main effects and interacted with Z_i . The model reduced the unexplained variance in classroom-level effects from 0.25 to 0.21—these variables explained about 27% of the unexplained variance in treatment effects. The coefficient on the interaction between pretest variance and reassignment—measuring the extent to which pretest variance explains treatment effects—was estimated as 0.09, with a 95% confidence interval of $[-0.75, 0.93]$, so the data are compatible with large associations in either direction between pretest variance and treatment effects. No firm conclusions may be drawn. The coefficient on the interaction between proportion reassigned and reassignment—measuring the extent to which classroom proportion reassigned ex-

Figure 5: The random effects γ_j from model (5) (with error bars for one standard error) as a function of classroom-level variance in pretest scores and the proportion of students in a classroom who were ever reassigned. OLS fits are added for interpretation.

plains treatment effects—was estimated as -0.3, with a 95% confidence interval of [-0.57,-0.03], and a p-value of $p = 0.03$. This suggests that the effect of reassignment may be lower—more negative—in classrooms in which a higher proportion of students were reassigned. This aligns with our second hypothesis.

These effect heterogeneity analyses assume (2), no unmeasured confounding. Unfortunately, we are not aware of methods for sensitivity analysis of the type presented in Section 6.1, applied towards estimates of effect heterogeneity. In particular, unobserved confounding may vary by classroom; for instance, the structure of the propensity score match may vary with the proportion of students ever reassigned, since within-classroom matches will be scarce when this proportion is high. For those reasons, the conclusions in this section should be taken as suggestive and exploratory.

7. DISCUSSION

A deeper understanding of the use of reassignment and its effects can yield practical and theoretical dividends. Teachers would benefit from clear guidelines as to when and whether reassigning students to a new section may benefit that student’s learning. A better understanding of if and when reassignment helps or hurts student learning can contribute to our understanding of the importance of sequence and mastery learning in intelligent tutoring systems.

Here, we estimate that, on average, reassignment hurts student learning, perhaps as much as CTA1 helps. That conclusion comes with two important caveats: first, although it appears unlikely that the entire reassignment effect we estimated is due to confounding from unmeasured variables, a large portion of the effect might be. That is, the magnitude of the reassignment effect we estimated may be an artifact of unmeasured confounding—reassignment may not be as bad

as we estimate, or it may be worse. (Of course, we cannot rule out that the entire effect is due to confounding, or that the direction of our estimated effect is wrong.)

Secondly, there is evidence that the effect of reassignment varies widely between classes. Even if it hurts on average, used properly it may help.

More broadly, these issues illustrate the opportunities and perils of analyses of log data from randomized trials of educational technology. Even when the randomization itself does not contribute to an analysis, the combination of log data collected under natural conditions and a long period of time and a posttest measuring student ability at the end of the study can be used to gain insights on tutor use and effects. On the other hand, log data, even from a randomized trial, is observational, and therefore messy and subject to confounding and other threats. Causal modeling of log data from randomized experiments is crucial, but difficult.

ABSTRACT

Supervised machine learning has become one of the most important methods for developing educational and intelligent tutoring software; it is the backbone of many educational data mining methods for estimating knowledge, emotion, and other aspects of learning. Hence, in order to ensure optimal utilization of computing resources and effective analysis of models, it is essential that researchers know which evaluation metrics are best suited to educational data. In this article, we focus on the problem of wrapper feature selection, where predictors are added to models based on how much they improve model accuracy in terms of a given metric. We compared commonly-used machine learning algorithms including naive Bayes, support vector machines, logistic regression, and random forests on 11 diverse learning-related datasets. We optimized feature selection based on nine different metrics, then evaluated each to address research questions about how effective each metric was in terms of the others (e.g., does optimizing for precision also result in good F1?) as well as calibration (i.e., are predictions produced by models accurate probabilities of correctness?). We provide empirical evidence that the Matthews correlation coefficient (MCC) produced the overall best results across the other metrics, but that root mean squared error (RMSE) selected the best-calibrated models. Finally, we also discuss issues related to the number of features selected when optimizing for each metric, as well as the types of datasets for which certain metrics were more effective.

Feature selection, Metrics, Machine learning, Student models

1. INTRODUCTION

Machine learning is a popular method for building predictive models that automatically estimate various aspects of learning. These models, in turn, can be applied to study the processes of learning or teaching, or to automatically

guide students as they learn. Training models is a complex process, however. The space of possible machine learning models is far too large to fully explore, and thus the search space is typically narrowed by focusing on candidate models that appear promising via some measure of correctness (agreement with ground truth labels, for supervised classification), such as Cohen's kappa or F_1 [16, 40]. One common methodological step that involves model selection (narrowing the search space) is *wrapper forward feature selection* [29], a process wherein features are added one at a time to a model based on which feature produces the largest gain in model correctness. Changing the correctness metric by which features are evaluated can have a significant impact on the final selected model (which we demonstrate in this paper); however, little is known about exactly what these impacts are for different correctness metrics. In this paper, we address this problem by performing feature selection based on different metrics and comparing the resulting models.

Previous work in the area of examining correctness metrics for educational data mining has largely focused on what those metrics reveal about models [40, 10]. Related work has shown, for example, that area under the receiver operating characteristic curve (AUC or AUROC) ignores the scale of model predictions [40], and that F_1 can be increased by over-predicting the positive class [10]. From such findings we can generate hypotheses about the properties of models that result from relying on those metrics during feature selection. For example, we might expect recall- and F_1 -based feature selection to favor models that over-predict the positive class. However, there is little empirical evidence to support such hypotheses, which we aim to provide in this paper.

We explore a wide variety of correctness metrics for feature selection, evaluating them on 11 education-related datasets, to empirically measure relationships between feature selection metrics and resulting models. We include well-known and extensively-used metrics like AUC, Cohen's kappa, and others, as well as metrics that are less-commonly used but perhaps equally valuable, like the Matthews correlation coefficient and the minimum proper AUC. We experiment with metrics and datasets across four commonly-used machine learning classifiers, including support vector machine, naive Bayes, logistic regression and random forest. These algorithms have been frequently applied with great success in educational data mining and related research [24, 21, 43, 9], including in situations where high-dimensional data require feature selection [27, 49, 34].

Debopam Sanyal, Nigel Bosch and Luc Paquette "Feature Selection Metrics: Similarities, Differences, and Characteristics of the Selected Models" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 212 - 223

To the best of our knowledge, ours is the first work to explicitly test differences between correctness metrics in the context of feature selection. Our results are valuable for future educational data mining research and practice by providing guidance to machine learning experts who wish to make evidence-based decisions about their model building methods. In particular, we characterize metrics in terms of the models that result from performing feature selection based on those metrics, which will help researchers decide on appropriate metrics based on the desired properties of their resulting models.

2. RELATED WORK

While previous research and other projects in this area is limited, there have been a few relevant research projects with findings that significantly informed our current work. In this section, we describe metrics evaluated in this study along with examples where they were used in previous work, then discuss directly-related work on evaluating metrics in educational data mining.

2.1 Metrics and their Usage

Accuracy. In this paper, accuracy refers to the proportion of correctly classified instances, though in other contexts it may refer more generally to any measure of how well a model's predictions align with ground truth values. Accuracy is one of the most straightforward metrics to calculate and understand, and thus has been reported frequently in machine learning studies [35, 12]. However, previous research has noted flaws with accuracy. In situations where labels are imbalanced, accuracy is often attenuated [25] or inflated [10] depending on the rate at which the model predicts the majority class. Despite possible flaws, it is commonly examined and is often the default correctness measure in machine learning software [39], including in wrapper feature selection software [41], so we include it in this paper.

AUC. AUC measures model correctness in terms of true positive rate across every possible false positive rate (i.e., across all possible decision thresholds). Chance level AUC is 0.5, while a perfect model has $AUC = 1$ and a completely incorrect model has $AUC = 0$. AUC is a valuable metric for its clear interpretability and effectiveness in the face of class imbalance [25], and has often been reported as an evaluation metric on educational datasets (e.g., [26, 23, 40, 37]). However, it only measures correctness in terms of the order of predicted values, not their scale [40], so it is unclear whether selecting features based on AUC will result in models that may have poorly-scaled predictions (an issue we explore in this paper). A related metric is the area under the precision–recall curve (AUPRC) [44], which also considers all possible decision thresholds. We have not yet included AUPRC in analyses, but expect that its behavior with respect to scale of predictions may be similar to AUC.

MPAUC. In situations where models provide only binary predictions, an approximation of AUC can be calculated by measuring the minimum proper AUC (MPAUC) of the quadrilateral formed by the single available decision threshold [38], as shown in Figure 1. We refer to this metric as MPAUC for the sake of brevity when reporting results, though it is not typically abbreviated in previous literature. It differs from AUC in that it measures the area for a “curve”

defined by a single point instead of many points as in AUC. Its advantage is that it is applicable even when continuous decision thresholds are not available. MPAUC has been utilized as a metric for feature selection in prior educational data mining research [9], but it is unclear how it compares to alternatives we explore in this paper.

Figure 1: Example MPAUC (shaded area).

MCC. The Matthews Correlation Coefficient (MCC) measures the correlation between two binary variables (predicted labels and actual labels) [30], and is equivalent to Pearson's r for two binary variables (i.e., ϕ). MCC ranges from -1 to 1, where 0 indicates chance level and 1 indicates perfect classification. MCC is especially useful in binary classification models where there is class imbalance, since its chance level is not affected by imbalance. MCC is simply a correlation coefficient between the true and predicted class. It is only defined for binary variables. While it is not common in educational data mining research, it has been occasionally reported [8, 1] and is valued in other machine learning fields [15].

Recall. Recall is the proportion of a certain label class (typically the positive class) that was correctly identified as being in that class [46, 4]. Recall is an informative measure for understanding model correctness, especially in situations where it is important to focus on one class (e.g., in situations where false negatives are costly). However, it can be inflated by over-predicting the positive class [10] and is thus not often reported as the sole measure of model correctness, so it is unclear whether it is appropriate as a metric for feature selection.

Precision. Precision is similar to recall; it is the proportion of instances predicted as being in the positive class that were correct predictions. Like recall, it is typically only reported in conjunction with other correctness metrics, but unlike recall it cannot be inflated by over-predicting the positive class [10]. However, in some cases it can be maximized by predicting the positive class for only a few of the highest-confidence instances.

F₁. F₁ is defined as the harmonic mean of precision and recall, and thus avoids some of issues of recall (favoring over-prediction of the positive class) and precision (under-predicting the positive class). However, it can be inflated by over-predicting the positive class [10], so it is unclear

whether selecting features based on F_1 will favor models that over-predict the positive class or not.

RMSE. RMSE (root-mean-square error) measures the Euclidean distance between predictions and ground truth labels. Since RMSE is an error metric, lower values are better, with 0 indicating no error. It is commonly associated with regression problems, since it can be easily calculated for continuous labels, but is also effective for binary classification with models that produce continuous-valued probability predictions [40, 13]. Previous research has noted that RMSE is especially effective for optimizing probabilistic predictions [40]; thus, we expect that selecting features based on RMSE might also produce models with well-calibrated probabilities (where model confidence matches the probability that the model is correct). Like AUC, RMSE does not require setting a decision threshold, unlike the other metrics we consider in this study. We refrained from using close variants like Mean Absolute Deviation (MAD) or Error (MAE), since previous work has noted issues with these metrics for model selection [40].

Kappa. Cohen’s kappa (κ) was developed as a measure of agreement between human annotators [16], but has often been utilized as a machine learning correctness metric by measuring the agreement between ground truth labels and predicted labels [10]. Like correlation measures, kappa ranges from -1 to 1 where 0 is random chance and 1 indicates perfect classification.

2.2 Research on Metrics in Educational Data Mining

Previous research has focused on metrics primarily in terms of the perspective that metrics have on a model of students, or on the properties of the model that are highlighted (or hidden) by particular metrics.

In one previous project, researchers focused on evaluating the properties of metrics that require continuous (probability-like) predictions [40]. In particular, they focused on AUC, RMSE, mean absolute error (MAE), and log likelihood (LL). They noted that for some applications (e.g., prediction of probability that a student has mastered a specific skill) metrics such as AUC do not favor well-calibrated models. They also compared metrics in terms of how often they agreed on picking the best model out of a pool of 20 simulated datasets, finding that RMSE and LL frequently agreed (17 out of 20) but others agreed much less often; the second-highest agreement was between RMSE and AUC, on 7 out of 20 datasets. This is especially relevant to the work in this paper, where we compare properties of metrics applied across 11 real-world datasets.

In similar previous work, researchers compared the properties of metrics that require binary or categorical predictions, rather than continuous predictions [10]. They noted that F_1 is influenced by the base rate of the positive class in data, in line with other research on Cohen’s kappa, AUC, and other metrics [25]. However, they also noted that F_1 (and recall) are influenced by the predicted rate of classifiers. This finding is especially relevant to the current research because it is possible that feature selection will favor models and features that tend to predict more of the positive class when

selecting based on these metrics.

3. FRAMING THE PROBLEM

The goal of this paper is, broadly speaking, to provide empirical results that illustrate the relationships 1) among different metrics, and 2) between metrics and models, when metrics are employed for forward feature selection.

Sequential feature selection is a type of wrapper (model-based) feature selection in which a feature is added to or removed from a model, the model is re-trained, and the quality of the feature in question is assessed based on improvement in model correctness (as measured by some metric). In this study, we specifically performed forward feature selection by adding one feature at a time, stopping when all features were added or when the model had not improved for three consecutive features, then returned the set of features with maximum correctness among all the combinations explored. Our work focuses primarily on the effects of utilizing different metrics for the step in which model correctness is assessed, which drives the entire feature selection process. We define four research questions (RQs) to explore this problem:

RQ1: When selecting features based on a specific metric, how do the results vary in terms of the other metrics? Addressing this question will inform decisions about which metric to apply during feature selection by showing the relationships between metrics. For example, some low-cost applications may benefit from high recall (e.g., automatically selecting the most relevant material for students to review) while other higher-cost applications may require high precision (e.g., automatically predicting when a teacher should intervene to redirect learning behaviors). In these examples, we may wish to optimize feature selection for different metrics, but it is crucial to understand how that might influence other metrics; e.g., does optimizing feature selection for AUC tend to produce models that are also good in terms of Cohen’s kappa, recall, and the other metrics?

To address RQ1 we define the *ranking* of a metric with respect to all the other metrics. Specifically, given a set of metrics \mathcal{M} , a selection metric $X \in \mathcal{M}$ has rank 0 with respect to another metric $Y \in \mathcal{M}$ if selecting features based on X results in the best¹ value of Y compared to selecting features based on all other metrics in \mathcal{M} . Likewise, a metric $Z \in \mathcal{M}$ has rank 1 with respect to Y if selecting features based on Z produces the second-best value of Y compared to all other metrics in \mathcal{M} , and so on. Generally, we expect that selecting features for some metric $X \in \mathcal{M}$ will have rank 0 with respect to itself (X), though this is not necessarily always true. Furthermore, some metrics may be generally better than others in terms of rank, if they tend to favor models with well-rounded properties that satisfy each metric. We thus calculate the *mean ranking* of each metric as the mean of all rankings for a metric with respect to itself and all other metrics (nine in total, in this paper), as a way to discover which feature selection metrics tend to yield models that satisfy the wide range of criteria imposed by different metrics.

¹“Best” meaning highest for most metrics, but lowest for RMSE since it is an error metric.

RQ2: How do different feature selection metrics impact model calibration? As previous work noted, some metrics do not penalize models for being poorly calibrated [40]. However, it remains unclear how large of an effect using different metrics during feature selection may have on the calibration of the resulting model. We address this research question by calculating CAL scores (described in Sec. 4.4) for models selected based on each metric [12].

RQ3: How do different feature selection metrics impact the predicted rates of models? Certain correctness metrics favor over- or under-prediction of the positive class more than others. For example, accuracy for a problem with imbalanced classes can be increased simply by biasing predictions of the positive class in the same direction as the imbalance in the data [10]. We might expect that relying on accuracy for feature selection could thus result in models that over or under-predict the positive class, but it is unclear how problematic these effects may be, which we measure in addressing this research question.

RQ4: Do some feature selection metrics tend to result in more parsimonious models (fewer features) than others? In addressing this research question, we further characterize the models that result from applying different metrics during feature selection, and highlight cases where feature selection may fail (by selecting too few features) or unnecessarily increase model complexity (by selecting an unusually large number of features).

4. EXPERIMENTS

We performed a variety of experiments to address our research questions, consisting of training and testing machine learning classifiers with forward feature selection. Experiments required approximately 11 months of continuous run time², given that we performed extensive hyperparameter selection with 4 classifiers, 11 datasets, and 9 feature selection metrics, as detailed in this section.

4.1 Classifiers

As mentioned in the Introduction, we trained models including random forest, support vector machines, naive Bayes, and logistic regression. These machine learning algorithms represent a variety of methods with differing assumptions and levels of flexibility, and which are frequently employed in educational data mining research [18, 5, 21, 43, 20, 7, 11, 45]. Moreover, with the possible exception of random forest, these models quite often benefit from feature selection to avoid problems of over-fitting (e.g., when a logistic regression has nearly as many parameters as instances) [33] and collinearity (e.g., when two very similar features incorrectly double the impact of a relationship in a naive Bayes model).

4.2 Cross-validation

We utilized student-level four-fold cross-validation, training each model on data from 75% of students and testing it on the remaining 25% of students, then repeating a total of four times until each student was in the testing data exactly once. This procedure ensured that data from the same student was

²Experiments were run on an Intel Core i7 4.2 GHz processor (using a single core) with 32 GB memory and 256 GB storage.

never present in training and testing at the same time, which was crucial given that some of our datasets had multiple instances per student.

We performed nested (within training data) student-level four-fold cross-validation for evaluating hyperparameters and selecting features. Specifically, for every possible combination of hyperparameters, we performed forward feature selection, then stored the best result from the feature selection process (according to the current selection metric). Finally, we retrained the model using the best set of hyperparameters, including the best features, on all training data, and applied it to the testing data. Hyperparameter selection and feature selection did not involve the testing set in any way.

There are two common strategies for evaluating the results of cross-validation. The first, *macro-level averaging*, consists of calculating the desired correctness metric for each fold and averaging across folds (four folds, in our case). The second strategy, *micro-level averaging*, involves storing the predictions of each fold and calculating the correctness metric once at the end based on all predictions. We evaluated both strategies to assess possible differences on the feature selection process.

4.3 Hyperparameters

We extensively tested common hyperparameters for each classification algorithm to ensure models had a chance to fit to the very different properties of our datasets (e.g., type of data, number of features, size of dataset).

For random forest we set the number of trees at 50 (significantly increasing this proved infeasible for an already-long run time). We varied the minimum number of samples required to create a branch in each tree, trying 5 different values (2, 4, 8, 16, or 32). This hyperparameter controls model complexity by restricting how fine-grained the decisions in each tree can be. We also varied the number of features randomly chosen for building each tree, testing 4 options including proportions of .25, .50, .75, and the square root of the number of features (the default setting). This hyperparameter controls how different trees are from each other in terms of the features from which they are trained. In total, there were $5 \times 4 = 20$ combinations of hyperparameters for random forest.

We trained SVMs with the radial basis function (RBF) kernel, which has a hyperparameter γ that controls the size (radius of influence) of each RBF kernel. We tried values for γ of 0.001, 0.01, 0.1, 1, and 10. Similarly, we tuned C , the SVM complexity hyperparameter, over the same set of 5 possible values. There were thus $5 \times 5 = 25$ hyperparameter combinations for SVM.

Naive Bayes has little in the way of hyperparameters to tune, apart from the distribution assumption to use. We assumed a Gaussian distribution for all models, and thus did not perform grid search across hyperparameters.

We trained logistic regression models with L_2 regularization, and tuned the strength of regularization as a hyperparameter over the space of 5 possible values: 0.001, 0.01, 0.1, 1, and 10.

Finally, we experimented briefly with hyperparameters related to class imbalance in the datasets, after noting that models frequently learned to only predict the majority class. We initially experimented with re-weighting instances of the minority class with higher weight set as a hyperparameter, but ultimately found that generating synthetic minority-class data via SMOTE (Synthetic Minority Over-sampling TEchnique [14]) was more consistently effective across our datasets without requiring hyperparameter tuning.

4.4 Measuring Model Calibration

Calibration refers to how well a model’s predicted probabilities match the probability that those predictions are correct. For example, given a set of 100 instances where model predictions are all ≈ 0.7 , we would expect 70 of the instances to be the positive class, and 30 to be in the negative class. If more than 70 are true positives, the model is under-confident for those 100 instances, while if fewer are true positives, the model is overconfident. Good model calibration is desirable so that predictions are interpretable as probabilities, allowing decision thresholds to be set in meaningful ways (e.g., triggering an intervention only if the model is at least 90% confident, knowing that it will thus result in a 10% false positive rate).

We measured calibration by calculating CAL scores [12]. The CAL score for a model is calculated by sorting all N instances according to predicted probability, then dividing into $N - 99$ sliding windows of 100 instances (sliding by 1 instance). For each window, we calculated the absolute difference between the base rate of the positive class for those 100 instances and the mean predicted probability for the same instances. The CAL score consists of the mean of those absolute differences across all windows, and can be interpreted as the mean absolute error in model confidence.

4.5 Datasets

4.5.1 Video-based Engagement Detection Datasets

We obtained six datasets from a study that measured students’ self-reported engagement during an essay writing task [31], during which students’ faces were recorded by a video camera. Students made verbal judgments of their engagement in the moment (concurrently) in response to auditory probes. One week later, they made retrospective judgments of their engagement by viewing video clips of themselves that were recorded during the essay writing task. There were 23 students who made a total of 530 judgments of engagement during the writing task and 1,325 retrospective judgments. Researchers extracted three sets of features from videos: 1) heart rate, estimated via photoplethysmography [32]; 2) animation units (ANUs), a set of facial feature descriptors provided by the Microsoft Kinect SDK, which are analogous to facial action units (AUs) [19]; and 3) local binary patterns in three orthogonal planes (LBP-TOP) [50], which capture facial textures and how those textures change over time.

There were thus two sets of labels and three sets of features, for a total of six video-related datasets. We refer to the two heart rate datasets as VIDEO-HR-C (concurrent labels) and VIDEO-HR-R (retrospective labels). Similarly, we refer to the two animation unit datasets as VIDEO-ANU-C and VIDEO-ANU-R, and the two LBP-TOP datasets as VIDEO-LBP-C and VIDEO-LBP-R.

4.5.2 Cognitive Tutor Algebra Datasets

We obtained two datasets from a study [36] in which 59 students interacted with a computerized learning environment called Cognitive Tutor Algebra [3]. Students used Cognitive Tutor Algebra for an entire year as part of their regular mathematics curriculum. Researchers labeled 10,397 sequences of student actions in the learning environment for the presence of “gaming the system” behavior, where students attempt to progress through material by exploiting features of the learning environment (e.g., requesting hints repeatedly, guessing many answers) [6].

Researchers extracted two sets of features. Pattern features captured the presence or absence of 60 different sequences of actions that were designed to be similar to patterns identified by domain experts. We refer to the dataset with pattern features as CTA-PF in this paper. The second set of features consisted of 25 count features. Count features captured the number of times 6 different actions occurred as well as the number of times 19 different events occurred. Events were identified by domain experts, and included things like pausing between attempts to answer a problem or trying to reuse an answer in multiple steps of a problem. We refer to the dataset with 25 count features as CTA-C in this paper.

4.5.3 Student Survey Datasets

Two additional datasets came from surveys obtained from 788 students at two different secondary schools during the 2005–2006 school year [17]. The survey consisted of 30 questions, including demographics, which school they attended (of two possibilities), and other variables. We one-hot encoded variables with categorical answers. Labels in both datasets consisted of course grades recorded on a 0–20 scale. We converted these to binary labels by splitting on the median into high and low grades, so that all datasets would be comparable binary classification problems.

One of the datasets came from students in a mathematics course (MATH, with 395 students) and the other from a Portuguese language class (PORTUGUESE, with 649 students). Some students were in both classes; thus, the total number of students was less than the sum of the classes.

4.5.4 Educational Process Mining Dataset

We also extracted features from an educational process mining (EPM) dataset. Students worked on electronics exercises in a software environment called DEEDS (Digital Electronics Education and Design Suite). Students’ actions in the learning environment were timestamped and logged, and included mouse movements, keystrokes, and information about the exercises being solved. Grade data were provided for five learning sessions, from which we extracted features including time spent on activities, number of actions, mean, standard deviation, and other summary features from problem-level data. In total, 115 students participated, but grades and action log data were not available for all students in every session. Grades were recorded on a numeric scale, though we again converted these to classification problems via median split to maintain consistency with other datasets.

5. RESULTS AND DISCUSSION

We focus results on the four research questions outlined in Section 3; we also provide model correctness results in the

Appendix, but do not focus on these results here since the goal of this work is to compare metrics rather than focus on improving over previously-published models. Our experiments to address the research questions included 4 different machine learning algorithms, 2 methods of calculating results during cross-validation, and 11 datasets. The different machine learning algorithms yielded similar patterns for our primary research question (RQ1), with only a few exceptions (Figure 2). Similarly, results differed little across macro- and micro-averaging methods (Figure 3). Thus, we aggregated across classification algorithms and averaging methods to address our research questions without unnecessarily dividing results into 8 (2 averaging levels \times 4 classifiers) subsets.

Figure 2: Mean ranking for each machine learning algorithm and feature selection metric. “Log. Reg.” refers to logistic regression.

Figure 3: Mean ranking for feature selection metrics when calculating results via macro-level versus micro-level averaging.

5.1 Mean Rankings

RQ1 asks *When selecting features based on a specific metric, how do the results vary in terms of the other metrics?* Results in Table 1 show that MCC was, on average, the best (lowest) across models and datasets. Mean ranking for MCC averaged 3.441 across all datasets, while AUC and MPAUC were similar with mean rankings of 3.468 and 3.476 respectively. Low rank for MCC indicates that, across 11 datasets,

selecting features based on improvement in MCC yielded better results (in terms of itself and the other 8 metrics) than selecting features based on any of the other metrics. Specifically there were 3.441 correctness metrics on average for which selecting features based on some metric other than MCC yielded better results than MCC.

Conversely, precision was the worst-performing metric in terms of producing good results for other correctness metrics, with a mean ranking of 5.672. Recall and accuracy both had mean rankings above 4, while all other selection metrics had rankings \approx 3.5.

There was also some notable variation across datasets. Possible causes of variations include the differing types of features in the datasets (binary, continuous, counts, etc.), class imbalance, and problem difficulty (e.g., signal to noise ratio). A handful of datasets had significantly lower mean rank values for a specific metric when compared other metrics and the average value across all datasets for the metric itself. For example, in the PORTUGUESE dataset, AUC was a particularly effective metric. AUC’s mean ranking was 1.764, indicating that selecting features based on AUC in that dataset was almost always better (in terms of itself and the other metrics) than optimizing for those metrics was. In other datasets like VIDEO-LBP-C, the best metric had a much higher mean ranking. Similarly, metrics like F_1 and Accuracy had unusually low mean rank values for the MATH and VIDEO-HR-R datasets, respectively. In such cases, one metric did not frequently outperform the others.

We also explored RQ1 visually by counting the number of datasets for which each metric had at least a certain ranking or better (Figure 4), much like constructing a receiver operating characteristic curve requires finding predictions above every possible threshold. In Figure 4, higher curves are better, indicating that there were more datasets where the metric had a desirable ranking. The curve for precision was clearly lowest, followed by recall and then accuracy. The rest of the metrics were similar to one another, though the consistency of MCC is apparent from the fact that it was the first metric to achieve a certain ranking across all datasets.

5.2 Probability Calibration

RQ2 asks *How do different feature selection metrics impact model calibration?* The features that are selected can influence how well it is theoretically possible to calibrate a model. For example, a model with two binary features can only output four possible values, and thus it is quite likely the model will be unable to output predicted probabilities that closely align with the true probability that the model’s prediction is correct or not.

Results show that RMSE easily produced the best results (Table 2), with a mean calibration score (CAL) of 0.166 and the best CAL score in 8 of the 11 datasets. Recall had the worst calibration score averaged across models and datasets, followed by precision, accuracy and F_1 .

5.3 Positive Class Predicted Rate

RQ3 asks *How do different feature selection metrics impact the predicted rates of models?* The predicted rate of models is in some respects related to model calibration, since

Table 1: Mean ranking for each metric and dataset. Lower is better, indicating that a metric, on average, yielded better results in terms of itself and the other metrics. Values range from 0 (selecting features for that metric always produced the best score in terms of itself and the other metrics) to 9 (the number of metrics). The best metric for each dataset is highlighted in green, while the worst is in red.

Figure 4: Step graph for mean rankings of metrics used for wrapper feature selection across all datasets. The left edge of the x axis indicates the best (lowest) ranking, while the right indicates the worst (highest). The y axis indicates the number of datasets that have mean rank $\leq x$.

a model that severely over- or under-predicts the positive class is unlikely to be well-calibrated (e.g., a model that always predicts 100% confidence for the positive class will have very poor calibration for any negative-class instances). Results reflect this calibration–predicted-rate relationship (Table 3), showing that selecting features based on recall resulted in the largest mean absolute difference between actual base rate and predicted rate (0.233), while RMSE was close to best (0.080). Selecting features based on accuracy (proportion correct) did not produce inaccurate predicted rates (mean absolute difference = 0.079), however, despite relatively poor model calibration.

For imbalanced datasets where classification is imperfect, accuracy can be inflated by over-predicting the majority class [10, 25]. However, Table 3 shows that selecting features based on accuracy did not have this effect, perhaps because we applied SMOTE to reduce the impact of class imbalance during training. Conversely, selecting features based on recall increased the positive class predicted rate for most datasets, since doing so can inflate recall regardless of the presence of class imbalance [10]. Similarly, selecting features based on precision often resulted in under-prediction of the positive class (10 out of 11 datasets).

5.4 Number of Features Selected

Selecting features based on precision yielded the fewest numbers on average (4.173), while selecting based on RMSE yielded the most (10.523). Selecting features based on AUC also yielded more features (10.006, on average) than other

metrics except RMSE.

These patterns are likely due to the fact that adding relatively unimportant features to a model will offer only marginal improvement, and may not be enough to shift predictions above or below the decision threshold. All of the metrics that require a decision threshold (accuracy, F_1 , kappa, MCC, MPAUC, precision, and recall) resulted in fewer features than the threshold-free metrics of AUC and RMSE. For example, adding a feature that applies to only a few instances may help push the probability decision for those few instances in the right direction, but may not change the binary decision for those instances and thus may not be selected when evaluating based on threshold-based metrics.

6. LIMITATIONS AND FUTURE WORK

There are a few limitations to the experiments in this paper. First, the datasets that we analyzed represent only a handful from among thousands of educational datasets that researchers and others have collected over the years. Our datasets are also quite diverse, measuring very different student characteristics. Thus, we have only a sparse sampling of the space of educational datasets, and datasets that vary notably from those reported on here could exhibit different trends. Future work is especially needed in this area to discover specific properties of datasets (e.g., number of features, type of features) that inform which metrics are likely to be successful for wrapper feature selection. Such analysis is only possible with a large enough number of datasets to enable statistical comparisons at the dataset level.

Second, the metrics we examined also only represent a subset of many possible. Many other metrics are closely related to those we studied (e.g., informedness, markedness, balanced accuracy), but may not exhibit exactly the same patterns. We selected a diverse mix of commonly reported metrics and some less-common metrics, all of which have been shown to be useful in previous research.

Third, we explored only four of the most prominent machine learning classifiers from among many possible options. We chose these classifiers because they are represented in many education-related research endeavors, but results for other classifiers may differ. Perhaps most importantly, deep neural networks are increasingly popular for educational data mining research [2, 28, 48, 47, 42], but were not considered here. Wrapper feature selection is perhaps less common for deep neural networks, given the high computational cost of model training, but correctness metrics often play a similar role in the model selection process for neural networks – for example, when deciding when to stop training a model. In future work we will explore issues of model selection for neural networks as well.

Fourth, averaging across the four classifiers is a limitation as well. While classifiers performed somewhat similarly, Figure 3 shows some exceptional cases. For example, kappa performed poorly with random forest, and precision performed well with logistic regression. As part of future work, we will explore classifier-based analysis of metrics in more depth, including statistical analyses (e.g., Friedman test) where we consider a large number of classifiers as judges that are ranking metrics.

Table 3: Mean predicted rate of the positive class for models with features selected based on each metric, for each dataset. Base rate indicates the actual proportion of the positive class in the dataset. The last row refers to the mean absolute difference between predicted rate and base rate across datasets. Green highlighting indicates the closest match to the true base rate, while red indicates the predicted rate furthest away in each row.

7. CONCLUSION

As the field of educational data mining develops, and machine learning becomes increasingly popular for modeling student outcomes, it is imperative to deeply understand each step of the process and the influence researchers' choices have on models. Our experiments offer insight into the large differences that can arise from machine learning design decisions, specifically for feature selection. We showed that selecting features based on some metrics is rarely advisable (especially precision), and that the choice of metric has impacts not only on correctness measures but on other important properties of the resulting models, including calibration and size (number of features).

We found that MCC produced the overall best results across the other metrics in terms of mean ranking as a measure of well-rounded correctness across metrics. MCC was not the best selection metric for all the datasets; in fact, it was the most effective only for 2 of the 11 datasets we analyzed in this study. However, it was more consistently well-ranked than the other metrics. On the other hand, RMSE produced the best-calibrated models, which can also be an important consideration for applying student models that might benefit from easily-adjustable decision thresholds.

Student models are the driving forces in adaptive learning software. Thus, enhancing them will lead to better software for students and teachers. The results of this project will enable researchers to more accurately build models which predict student outcomes by informing the correctness metrics relied upon for feature selection. In particular, we suggest utilizing metrics like MCC and RMSE (if calibration is desirable) to yield models with well-rounded accuracy across metrics. We suggest avoiding recall, precision, and accuracy, even though accuracy is the default setting in some machine learning software.

APPENDIX

A. OVERALL CORRECTNESS AND COMPARISON TO PREVIOUS RESULTS

In this appendix we provide the correctness results obtained from our experiments, as a point of comparison to previous work and for comparison in future work. We report results where we selected features via MCC, since that metric had the best mean ranking in terms of other metrics (Table 1). We report only macro-level averaging, though results were similar for micro-level averaging (Figure 3). We also average results across all four classifiers, rather than selecting only the best classifier (and thus potentially introducing Type I error).

Table 5 shows the overall correctness metrics, with comparisons to previous work (where possible) noted by highlighted colors. For MATH and PORTUGUESE datasets we could not make direct comparisons because previous results did not perform median splitting to transform regression to binary classification. The feature selection criterion (which metric was used for selection) used by previous analysis is not clear in most cases. Hence, it is difficult to make close comparisons to previous models.

For the VIDEO-* datasets we compared AUC to [31]. In [31], AUCs reported were VIDEO-ANU-C: 0.635, VIDEO-HR-C: 0.544, VIDEO-LBP-C: 0.645, VIDEO-ANU-R: 0.666, VIDEO-HR-R: 0.590 and VIDEO-LBP-R: 0.644.

For the CTA-C dataset we compared AUC and kappa to [36]. However, the other models in this paper include feature-level fusion of both CTA-C and CTA-PF features, so they are not directly comparable to the CTA-PF features that we have. Reported values for CTA-C were AUC = 0.865 and kappa = 0.332.

For the EPM dataset we compared results to [22], which reports accuracy, F1, kappa, RMSE, precision and recall. However, accuracy, F1, precision and recall are reported for the random division and the alpha-investing feature selection methods and hence are not comparable to our results. The values (averaged across the reported models) were kappa = 0.443 and RMSE = 0.490, though the division of grades into two categories may have been based on a different split value than we utilized in this paper (the median), so comparisons should be made with that in mind.

Table 5: Our results for all metrics and datasets using MCC as the selection metric and macro-level averaging. Where previous results are known, green highlighting indicates that models we trained were better (more accurate) and red indicates that they were worse. Specific previous results are reported in the Appendix text.

Dataset	Accuracy	AUC	F1	Kappa	MCC	MPAUC	Precision	RMSE	Recall

ABSTRACT

One of the most challenging issues for online courseware engineering is to maintain the quality of instructional components, such as written text, video, and assessments. Learning engineers would like to know how individual instructional components contributed to students' learning. However, it is a hard task because it requires significant expertise in learning science, learning technology, and subject matter pedagogy. To address this challenge, we propose an innovative application of reinforcement learning (RL) as an assessor of instructional components implemented in given online courseware. After students activities are converted into Markov decision process (MDP), a collection of actions (each corresponds to an instructional component) suggested as a policy is analyzed. As a consequence, the usefulness of individual actions with regards to achieving ideal learning outcomes will be suggested. The proposed RL application is invented for human-in-the-loop learning engineering method called RAFINE. In the RAFINE framework, a machine generates a list of the least contributing instructional components on the given online courseware by interpreting the whole policy. The courseware developers modify those suggested components. As a proof of concept, this paper describes an evaluation study where online learning was simulated on hypothetical online courseware. The results showed that over 90% of ineffective instructional components were correctly identified as ineffective on average.

1. INTRODUCTION

With the rapidly growing popularity of online courses, there has been a heavy demand for practical learning engineering methods for designing effective online courseware [18]. Even though there are known design principles that provide theoretical insights into designing effective online courses [e.g., 5, 6, 10], such principle-

based approaches still require iterative engineering for practical courseware development at scale [8].

One of the challenges in the principle-based iterative learning engineering is to identify issues with the courseware. After an initial version of courseware is used by students, instructors (or learning engineers) analyze the interaction and learning outcome data to improve the quality of the courseware. However, interpreting those data to determine actual refinement plans is extremely challenging and requires significant expertise in learning science, learning technology, and the subject matter pedagogy [5, 20]. The commonly used analytic techniques are the learning curve analysis [14] and the assessment items analysis [16]. However, these techniques only apply to assessment items while other types of instructional components such as video clips and written texts must also be included in the analysis.

There is therefore a gap between an ideal learning-engineering model to *efficiently* build *effective* online courseware and the actual technology infrastructure available for building online courseware. To fill this gap, evidence-based learning engineering method that identifies deficits of the given online courseware is needed.

Our solution is an innovative application of the reinforcement learning (RL) technique that we call RAFINE (Reinforcement learning Application For INcremental courseware Engineering). RAFINE identifies instructional components that have relatively less contribution to students' learning in the given courseware. RAFINE is a building block for the evidence-based, human-in-the-loop, iterative learning engineering method that we call the RAFINE method. Figure 1 shows how a human and a machine collaborate to iteratively improve the quality of courseware in the RAFINE method.

Given a record of individual students' learning trajectory logs on particular online courseware, RAFINE first converts learning trajectories into a state transition graph. Here, states represent students' intermediate learning status and the transition is caused by taking an instructional component (i.e., watching a video). All students' state transition graphs are then consolidated into a single Markov decision process (MDP) by merging the same states. RAFINE then applies a variant version of value iteration technique commonly used for RL to compute a *converse policy* that represents the least optimal instructional components to be taken at any given moment to achieve students' ideal learning goals. The entire policy actions will be then analyzed to identify instructional components that have relatively less contributions to students' learning. The list of detected less-effective components is provided to instructors as a *recommendation* for courseware refinement. Any type of

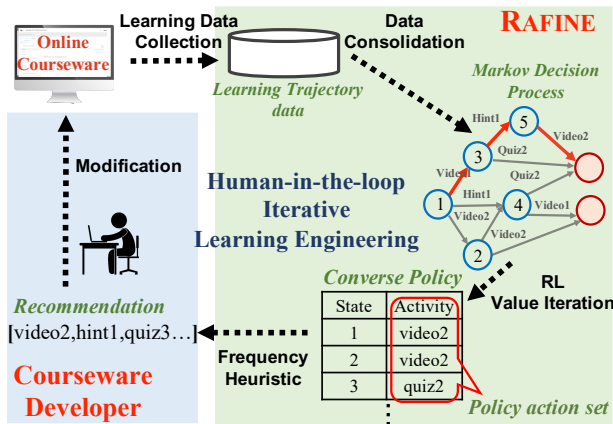

Figure 1 : Overview of the RAFINE method

instructional components such as lecture videos, assessment quizzes and hints can be analyzed by the RAFINE method.

As a proof of concept, the goal of the current paper is to conduct a study to evaluate the validity of implementation of the RAFINE method. We conducted a simulation study where learning log data were generated by simulating learning activities in mock online courseware. The result showed that the RAFINE method correctly identified over 90% of ineffective instructional components in the given mock courseware.

The primary contributions of the current work are essentially theoretical yet have the potential for practical use:

- (1) We proposed RAFINE as a building block for evidence-based, human-in-the-loop, iterative online courseware learning engineering method. RAFINE analyzes complicated learning trajectory data and suggests deficits of the courseware by evaluating a broader range of instructional components. The evaluation study showed the theoretical effectiveness of RAFINE.
- (2) We innovated a technique to interpret a policy induced by reinforcement learning as a whole to detect a relative weakness among available actions (which correspond to instructional components) with regard to achieving ideal goals.

The rest of the paper is structured as follows. Section 2 discusses related work on evidence-based learning engineering and the applications of reinforcement learning for education. Section 3 technically elaborates how RL works on learning trajectory data and describes how RAFINE interprets the converse policy. Section 4 introduces research questions. Then, section 5 explains how simulation data were created for the evaluation study. Section 6 reports results of the evaluation study along with the research questions, and section 7 discusses the results and limitations. Finally, section 8 concludes that RAFINE serves as a building block for the evidence-based iterative learning engineering method.

2. RELATED WORK

2.1 Evidence-based Learning Engineering

The process of learning engineering includes cognitive task analysis, designing and delivering instructional components, measuring students' understanding, and evaluating the courseware design [6]. Quickly cycling through these tasks is a key for successful iterative improvement of online courseware. Since each of these tasks is considerably labor intensive, the automatization of the engineering process is an important research agenda.

One of the most actively studied areas of learning engineering is student modeling [14]. Both a representation (to understand what must be modeled) and a recognition (to understand how to gauge students' competency with the proposed representation) are important research topics. Cen *et al.* [3] proposed Learning Factors Analysis (LFA) for semi-automated evaluation and improvement of knowledge component (KC) models that represent a set of latent skills and knowledge that students are supposed to learn [12]. LFA performs a combinational search for a KC model that best fits students' learning data across existing KC models. Although LFA requires "seed" KC models, some more recent works reported automatic discovery of KC models from students' learning data [9, 13].

Another actively studied area of learning engineering is an automated question generation. Du and Cardie [7] proposed a method for automatically generating questions. The method identifies the question-worthy sentences from a passage using a hierarchical neural model with a sentence-level sequence tagging. Mazidi and Tarau [15] introduced a method to classify sentences based on what the sentence is communicating as a basis for generating questions. The type of syntactic and semantic constituents of sentences and their arrangement were analyzed in the study.

Automation of assessment grading is also an important part of learning engineering in particular for online courses to be scaled. Zhang *et al.* [25] tackled the task of Automatic Short Answer Grading (ASAG). Short answer questions ask students to answer in natural language with the length of one phrase to one paragraph. The authors compared Deep Belief Networks (DBN) against five machine learning techniques (Naïve Bayes, Logistic Regression, Decision Tree, Artificial Neural Network, and Support Vector Machine) for automatically grading short answer questions.

Yet another essential part of practical learning engineering is to identify deficits of courseware content to be revised. RAFINE focuses on this aspect of the learning engineering. As far as the authors are aware, there have been very few studies in this line of research. Bodily *et al.* [2] mentioned the lack of efforts to use learning analytics as a basis for redesigning an online course. The authors proposed the RISE framework for redesigning instructional components in online courseware. This framework provides a metric that combines the usage of instructional components and students' grades to identify instructional components that are good candidates for improvement efforts. The goal of the RAFINE method is also to detect instructional components that were not very useful for learning. Unlike the RISE framework, however, RAFINE evaluates a potential contribution of implemented instructional components to students' learning and provides a list of instructional components as a recommendation for refinement.

2.2 RL for Decision Making in Education

Reinforcement Learning (RL) has been used in education applications in particular to compute optimal pedagogical strategies for adaptive tutoring.

Shen and Chi [19] applied RL to induce the policy on whether the intelligent tutoring system should propose worked example (WE) or problem solving (PS) to students for the next activity. The authors induced policies using two different rewards: Immediate and Delayed. The policy was computed based on the number of problems solved, the average time taken, the difficulty of the problem, and students' performance on the past PS. The result

showed that immediate policies give more WE while delayed policies give more PS.

Rafferty *et al.* [17] used the partially observable Markov decision process (POMDP) framework to formulate the process of teaching. The authors applied RL to induce optimal teaching actions such as a quiz or an example to minimize the amount of time spent on learning materials. They found that students who learned with RL induced teaching actions spent less time than students who did not.

Iglesias *et al.* [11] applied RL to induce a policy on teaching decisions such as which topic students should do next and which task students should do on the topic. They conducted an evaluation study in a database design course for undergrad students in Computer Science. In the evaluation study, they found that students with the machine generated policy spent less time on the adaptive and intelligent educational system, but they could not find a significant difference in the students' final level of knowledge.

In addition to inducing the sequence of instructional components, RL has been applied to induce dialog moves or narrative events. Chi *et al.* [4] applied RL to induce pedagogical policies that decide whether the tutor should ask students to justify the answer, tell the next step directly, or elicit the next step information from a student in a dialogue-based tutor. Tetreault and Litman [21] estimated the reliability of a policy derived from a spoken dialog tutoring system. Wang *et al.* [22] applied deep RL for interactive narrative generators that tailor each player's story in an educational game. The authors prepared several events of a story and induced policies on how event sequences should unfold based on player interaction logs.

The applications of reinforcement learning to induce pedagogical strategies are widely studied in various subjects from middle school math to college-level database design, and in various kinds of tutoring systems such as task-based, dialog-based, and game-based systems. The effects of educational RL policy have been tested both with real and simulated data. Some showed positive effects of the policy while others did not.

What makes our study different from these studies is the way we use the induced policy. In the previous studies mentioned above, the induced policy is directly used to provide an *optimal action at each learning status*. On the other hand, RAFINE does not use the policy to make a decision on which instructional component students should take next. Instead, RAFINE interprets the induced policy as a whole to identify instructional components that have relatively less contribution to learning. More specifically, RAFINE focuses on how often each instructional component is suggested by a policy (we call this the *frequency heuristic* as described in section 3.5). In RAFINE, the induced policy is not utilized as an educational strategy for students, but an analysis of the policy is used for courseware developers to improve courseware.

3. TECHNICAL DETAILS OF RAFINE

3.1 Overview of the RAFINE Method

In the RAFINE method, an initial version of the online courseware is used by students and their activities are logged. These activity data consist of standard clickstream data including students' responses for formative assessments and their correctness. We call these activity data the *learning trajectory data*.

The right side of Figure 1 shows how learning trajectory data are processed. The learning trajectory data from all students are first consolidated into a single state transition graph called *learning trajectory graph* (LTG). The LTG is a Markov decision process

(MDP) where states represent students' intermediate learning status and actions represent instructional components taken. LTG is annotated with predefined *rewards* that represent quantitative benefits of the learning activity that causes transition from one state to another in the LTG. Finally, a value iteration technique is applied to compute a *converse policy* that shows the worst action to be taken at each state to achieve the expected learning outcome (represented as a table in Figure 1). As a consequence, a collection of actions suggested by a converse policy corresponds to a set of instructional components that have the least likelihood at each state to contribute to the ideal learning outcome. We call this collection of actions the *policy action set*.

To create a recommendation for refinement based on the induced policy, RAFINE *interprets the policy as a whole*. That is, all actions in a policy action set is analyzed. Note that in most cases, the number of states in the LTG gets larger than the number of instructional components available on the given online courseware. This implies that all instructional components are likely to be included in a policy action set. The relative effectiveness of individual instructional components is therefore analyzed based on the frequency. We call this heuristic the *frequency heuristic*, which is detailed in section 3.5.

Given the recommendation for refinement, courseware developers revise the courseware. The RAFINE method can be iteratively applied to the revised courseware by collecting a new batch of learning trajectory data to further improve the courseware.

3.2 Model Representation

The unit of analysis of the RAFINE method is an instructional component implemented in the online courseware. Instructional components include video, quiz, hint, written paragraph or any other components used in the courseware. We assume a presence of a skill model that contains a set of skills each representing a piece of knowledge that students must learn (aka, knowledge component), and each instructional component is tagged with a single skill. Under this assumption, RAFINE will be applied for each skill separately. This constraint is rooted in our design decision for a state representation described later that involves a measure of proficiency per skill.

Let LT_i^ϕ be a given learning trajectory for student i regarding skill ϕ . Let a_i^T be an instructional component taken (e.g., watching a video or answering a quiz) by student i at time T . A learning trajectory for student i on skill ϕ , LT_i^ϕ , is represented with a_i^T as follows:

$$LT_i^\phi = \{a_i^1, \dots, a_i^{n_i^\phi} \mid a_i^T \in \Phi^\phi, T = 1, \dots, n_i^\phi\}.$$

LT_i^ϕ : learning trajectory for student i regarding skill ϕ

a_i^T : an instructional component taken by student i at time T

Φ^ϕ : a set of instructional components regarding skill ϕ

n_i^ϕ : number of activities taken by student i regarding skill ϕ

To make the explanations simple, without a loss of generality, let's assume that there is only one skill ϕ in our target online courseware (recall that RAFINE will be applied for individual skills separately). We therefore eliminate the skill index from Φ^ϕ and LT_i^ϕ in the following descriptions unless otherwise desired.

All learning trajectories LT_i for all students i in the given log data are consolidated into a single learning trajectory graph (LTG), which is an MDP. In the LTG, states represent learning status and

edges represent learning activities taken that caused a change in learning status. To consolidate individual students' learning trajectories into a single LTG, each student's learning trajectory LT_i is first converted into a *learning trajectory path*. This is done by chronologically traversing a learning trajectory LT_i while creating states that represent intermediate learning status.

A learning status consists of a pair of *action history* and *mastery level*; $\langle \mathbf{ah}_{i,T}, p_{i,T}(\phi) \rangle$. Action history $\mathbf{ah}_{i,T}$ is a binary vector $\langle ah_i^1, \dots, ah_i^K \rangle$ where ah_i^m shows whether student i has taken the m -th instructional component in Φ^ϕ by time T (assuming the instructional components are ordered and $|\Phi^\phi| = K$). Mastery level $p_{i,T}(\phi)$ is a scalar value showing a predicted probability of student i applying skill ϕ at time T correctly. The value of mastery level is rounded to the nearest multiple of 0.05 (e.g., 0.12 becomes 0.10) to reduce the number of states in the LTG (which will be otherwise intractable).

Mastery level is computed based on the history of learning activities. An underlying assumption is that commitment to a particular type of learning activity would increase the mastery level by a specific amount. There are several known techniques available to achieve this goal including Bayesian models and regression models. As long as mastery level is monotonically updated, any student-modeling technique would work for the RAFFINE method.

While traversing the learning trajectory, $\mathbf{ah}_{i,T}$ and $p_{i,T}(\phi)$ are updated accordingly. For example, assume there are six instructional components; Video1, Video2, Quiz1, Quiz2, Hint1, and Hint2. A state $s \langle 101000, 0.4 \rangle$ indicates that a student had watched Video1 and took Quiz1 before reaching the state s . It also indicates that a predicted mastery level for skill ϕ at the time of arriving at the state s was 0.4. Assume that the student answered Quiz1 incorrectly to reach the state s . Now, the student needed to review Hint1, which caused a transition from s to s' where s' is $\langle 101010, 0.45 \rangle$ with an assumption that reviewing a hint increased the master level by 0.05.

A learning trajectory path is a linear graph. It might have a loop back to the same state when a certain instructional component was taken more than once with the increase of mastery level less than 0.05. As a side note, moving between pages in the courseware is not encoded in the LTG, because it is not considered as a learning activity.

All individual students' learning trajectory paths are then aggregated into an LTG by merging the same states. As a consequence, the states in an LTG generally have multiple incoming and outgoing edges. Note that in an LTG, student and time (i.e., the parameters i and T in an individual student's learning trajectory path) are abstracted. Therefore, in the following explanations, a tuple representing a state is denoted as $\langle \mathbf{ah}, p(\phi) \rangle$.

In an LTG, the states where the value of the mastery level, $p(\phi)$, is greater than a pre-defined threshold (which is usually 0.85) are called *terminal states*—meaning that students became proficient in applying skill ϕ . All outgoing edges at terminal states are discarded.

3.3 Reward

A reward value of a particular state depends on the mastery level, $p(\phi)$, both at the current and successor states. As an example, consider two students who landed on the same state s , but then took different learning activities. One student reached a successor state by answering an assessment quiz incorrectly (i.e., $p(\phi)$ was not increased) whereas the other student watched a video (i.e., $p(\phi)$ was

increased). In our model, a reward for state s where the student took a learning activity a to reach a successor state s' is defined as:

$$R(s, a, s') = \begin{cases} -0.14 & (ml(s) = ml(s') < 0.85) \\ -0.05 & (ml(s) < ml(s') < 0.85) \\ 0.95 & (0.85 \leq ml(s')) \end{cases}$$

In the equations above, $ml(s)$ returns the mastery level at the state s . A reward at the state s becomes the greatest when the successor state is a terminal state. Otherwise, the rewards are set to be small negative values to reflect students' time commitment while computing a policy as shown in the next section. We assume that the mastery level grows monotonic, i.e., students never unlearn. Therefore, a reward where $ml(s) > ml(s')$ is undefined.

3.4 Converse Policy

Given the reward function R , a value function for state s under a policy π is defined as follows, where \mathbf{S} is a set of all states in a given LTG:

$$V^\pi(s) = \sum_{s' \in \mathbf{S}} T(s, \pi(s), s') \{R(s, \pi(s), s') + \gamma V^\pi(s')\}$$

In the current implementation, the discount factor γ is arbitrarily set to be 0.9. A transition model $T(s, a, s')$ is derived from the collected learning trajectory data of actual students as the probability of students reaching state s' when they took a learning activity a at state s .

In general, a policy suggests an action to be taken in a certain state to maximize the value function [23]. However, considering the purpose of RAFFINE, we need to know which instructional components should not be taken—i.e., we need to know which action has the least expected reward. Therefore, through the value iteration, the value function is updated as follows where $A(s)$ shows a set of actions available at state s (i.e., instructional components taken by students at state s):

$$V(s) \leftarrow \min_{a \in A(s)} \sum_{s' \in \mathbf{S}} T(s, a, s') \{R(s, a, s') + \gamma V(s')\}$$

After the value function is converged, the action that minimizes the value function for state s is identified. We shall call this policy the *converse policy*:

$$\pi(s) = \operatorname{argmin}_{a \in A(s)} \sum_{s' \in \mathbf{S}} T(s, a, s') \{R(s, a, s') + \gamma V^\pi(s')\}$$

3.5 Frequency Heuristic

Because of the binary vector and mastery level in the state representation, the number of states in any given learning trajectory graph (LTG) is many times more than the number of available actions (i.e., instructional components). Hence it is often the case that each of the instructional components in the courseware is selected as a policy action many times. Therefore, whether the instructional component has been selected as an action is not a sufficient criterion to decide the component should be included in a recommendation for refinement.

To create a recommendation from the induced converse policy, RAFFINE interprets the collection of policy actions over all states in the LTG based on a frequency—*actions that frequently appear in the converse policy action set* will be included in a recommendation as culprit for poor performance. We call this heuristic the *frequency heuristic*. The frequency heuristic is based on the hypothesis that relatively ineffective instructional components tend to appear in a

policy action set of a given converse policy more frequently than effective ones. We will verify this hypothesis by comparing the mean normalized frequency of ineffective and effective components in the policy action set.

The empirical question is then “how frequent is frequent?” We examined two frequency cut-offs through an evaluation study as described in the results section.

4. RESEARCH QUESTIONS

Our central question is whether RAFINE can suggest deficits of the courseware based on the students’ learning trajectory data. To address this question, we divide it into the following two research questions:

RQ1: How robust is the converse policy as a detector for relatively ineffective instructional components against different conditions of learning data?

RQ2: How accurately does the frequency heuristic compose a recommendation for courseware refinement?

To answer these questions, and also as a proof of concept for RAFINE, we conducted an evaluation study as described in the next section.

5. EVALUATION STUDY

For a rigorous evaluation of the RAFINE method, it is necessary to conduct a study with learning data collected from students working on actual online courseware. As mentioned earlier, the online courseware must be structured with a skill model tagged to individual instructional components to apply RAFINE. To the authors’ knowledge, however, no such online courseware is available at this moment and building RAFINE compatible online courseware requires a considerable amount of time. Therefore, we conducted a simulation study as a proof of concept towards an evaluation with actual students. The current evaluation study uses hypothetical learning trajectories in mock online courseware. The results from the current simulation study justify future efforts of building an RAFINE compatible online courseware or tagging a KC model to individual instructional components in existing courseware.

In this evaluation study, we address the research questions mentioned in section 4. We created mock online courseware where there was only one skill involved. As described above, when there were multiple skills involved, RAFINE had to be applied separately to each skill. Therefore, this assumption does not harm the generality of the study.

All instructional components in mock online courseware were tagged as either *effective* or *ineffective*. In the current simulation study, we included three types of instructional components: (1) videos, (2) formative assessments (aka quizzes), and (3) hint messages associated with formative assessments. Learning trajectories were generated by simulating students’ learning activities. For the sake of explanation, we use a phrase ‘simulated students’ to refer to hypothetical students in the simulation.

In the real world, the growth of mastery level depends on the learning activities actually taken and students’ latent traits of learning. In the current simulation, the mastery level shows a probability of answering a quiz correctly and the simulated students’ performance on a quiz was determined by the mastery level. The growth of the mastery level, $p_{i,T}$, was simulated using a logistic regression model as shown below:

Table 1: The means μ and standard deviations σ used for the simulation study to model the growth of mastery level.

(a)

The value of (μ_1, σ_1) where

$$\delta_1(c, e(a_{i,T-1})) \sim \max(0, \mathcal{N}(\mu_1, \sigma_1^2))$$

	Contrast: c			
Effectiveness: $e(a_{i,T-1})$	Large		Moderate	Small
Effective	0.5	0.01	0.4	0.05
Ineffective	-0.1	0.01	0.0	0.05

(b)

The value of (μ_2, σ_2) where

$$\delta_2(\text{rspns}(a_{i,T-1})) \sim \max(0, \mathcal{N}(\mu_2, \sigma_2^2)), \text{ or } 0 \text{ if } a_{i,T-1} \text{ was not a quiz.}$$

$\text{rspns}(a_{i,T-1} \in \text{quiz})$	μ_2	σ_2
Correct	0.05	0.01
Incorrect	0.03	0.01

Table 2: The means and standard deviations used for computing the initial logit $Z_{i,0}$.

The value of (μ_0, σ_0) where $Z_{i,0} \sim \max(0, \mathcal{N}(\mu_0, \sigma_0^2))$

	Contrast: c		
	Large	Moderate	Small
μ_0, σ_0	-0.95 0.01	-0.95 0.10	-0.95 0.20

$$p_{i,T} = \left[\frac{1}{1 + e^{-Z_{i,T}}} \right]$$

$$Z_{i,T} = Z_{i,T-1} + \delta_1(c, e(a_{i,T-1})) + \delta_2(\text{rspns}(a_{i,T-1}))$$

The $[X]$ operator is to round the value X to the nearest multiple of 0.05 and $a_{i,T-1}$ is an instructional component that a simulated student i took at time $T-1$.

Logit $Z_{i,T}$ was directly increased with $\delta_1(c, e(a_{i,T-1})) + \delta_2(\text{rspns}(a_{i,T-1}))$. δ_1 and δ_2 model learning gain obtained by taking an action $a_{i,T-1}$. $\delta_1(c, e(a_{i,T-1}))$ is a rectified random variable that follows a normal distribution with mean μ_1 and standard deviations σ_1 , i.e., $\max(0, \mathcal{N}(\mu_1, \sigma_1^2))$. μ_1 and σ_1 are given a priori based on c and $e(a_{i,T-1})$.

c and $e(a_{i,T-1})$ that represent *contrast* and *effectiveness* respectively were the parameters controlled to create several online learning scenarios for research question RQ1. We controlled the difference in impact on students’ learning (i.e., mastery level) between effective and ineffective instructional components using two parameters: (i) c that represents the *contrast* in the increase of logit between effective and ineffective instructional elements—large vs. moderate vs. small, and (ii) $e(a_{i,T-1})$ that represents the *effectiveness* of the instructional element $a_{i,T-1}$ —effective vs. ineffective.

The fundamental assumptions were that (1) the larger the contrast, the larger the differences of μ_1 when effective vs. ineffective instructional components were taken, and (2) the larger the contrast, the smaller the σ_1 was. For example, if c = “large”, (μ_1, σ_1) was (0.5, 0.01) vs. (-0.1, 0.01) for $e(a_{i,T-1})$ = “effective” vs. “ineffective.” However, they were (0.3, 0.1) vs. (0.1, 0.1) if c = “small.” Table 1(a) shows μ_1 and σ_1 for different *contrast* and *effectiveness*.

$\delta_2(\text{rspns}(a_{i,T-1}))$ is also a rectified random variable that follows a normal distribution with mean μ_2 and standard deviations σ_2 . The variable δ_2 was set to be zero if $a_{i,T-1}$ was not a quiz. Otherwise, μ_2 and σ_2 were determined a priori based on a student’s response

rate, $rsps = \text{correct}/\text{incorrect}$. We assume that when a student was able to answer the quiz correctly, $\text{logit } Z_{i,T}$ increases more than when the student was not able to answer it. Table 1(b) shows μ_2 and σ_2 for correct and incorrect responses respectively.

Student's initial $\text{logit } Z_{i,0}$ also followed a rectified normal distribution with μ_0 and σ_0^2 . These were given a priori based on the contrast parameter, c , as shown in Table 2.

In addition to three learning scenarios with different *contrasts*, we also created three versions of mock online courseware with different *qualities*. The quality of courseware was operationalized as the ratio of a number of effective to ineffective instructional components in the courseware. Three types of qualities are implemented in this study: High, Medium and Low. The higher the quality, the larger the proportion of effective instructional components. In the simulation study, each page in the mock online courseware included 3 lecture videos, 3 quizzes, and 3 hint messages each associated with a quiz. The low, medium, and high-quality courseware included 80-90%, 50-60%, and 10-20% ineffective instructional components.

Two instances of mock courseware (with a different number of pages) were created for each level of quality. Those six instances of courseware were crossed with three levels of contrast, resulting in 18 different simulated-learning scenarios. In each scenario, simulated students took a total of 10 to 30 instructional components.

Learning trajectories of students were randomly generated as follows. At first, for each simulated student, the number of instructional components to be taken was randomly decided. Either a video or a quiz was then randomly selected as the first learning activity. If it was a quiz, the student might show a hint before trying to answer the quiz at 0.05 probability. When the student answered a quiz, the correctness of the quiz response was determined randomly using the mastery level as the probability distribution. When the response was incorrect, either requesting a hint or retaking the same quiz (as a next instructional component) was randomly determined based on the probability distribution reported in [1]. Let quiz_x be a quiz with an ID x that student answered incorrectly. The probability distribution is as follows: (i) Try quiz_x at 0.78 probability, (ii) show hint_x at 0.20, (iii) give up and move to different quiz or video at 0.02 (these two are randomly selected). The same distribution is applied when the student showed hint_x . This process was repeated for the number of instructional components to be taken. Simulated students were able to retake the same instructional components.

For each of 18 learning scenarios, 100 course offerings were created each with 1,000 simulated students. In other words, this simulation study modeled a large-scale field trial as if 1800 instances of online course offerings were tested each with 1,000 student participants.

For each course-offering simulation, the learning trajectory data were converted into a learning trajectory graph (LTG). As a consequence, 1,800 instances of LTGs were generated. The manipulation of logit described above was used to estimate mastery level in LTG. For each of the 1,800 LTGs, the value iteration technique was applied to compute a converse policy. From each converse policy, the frequency heuristic was applied to generate a recommendation for refinement for a corresponding instance of online courseware.

6. RESULTS

6.1 Overview of the Data

To verify the feasibility of the simulation data, we computed a correlation between the ratio of effective to ineffective instructional components taken by a student and the final mastery level. The data showed a strong positive correlation, $r = 0.70$, $t(1799998) = 1314.56$, $p < 0.001$, suggesting that the final mastery level was significantly higher when simulated students took relatively more effective instructional components than ineffective ones.

6.2 Converse Policy-based Recommendation

6.2.1 Frequency Heuristic

The hypothesis under the frequency heuristic is that relatively ineffective instructional components tend to appear in a policy action set of a given converse policy more frequently than effective ones. To verify this hypothesis, we first compare the normalized frequency of ineffective components in the policy action set with that of effective ones. We also answer RQ1: How robust is the converse policy as a detector for ineffective instructional components against different conditions of learning data?

The frequency of an instructional component i selected as a converse policy action was normalized as follows. Let π be a converse policy and S be the set of states in the LTG. The normalized frequency of an instructional component i is calculated by the following equation.

$$\text{Normalized Frequency}(i) = NF(i) = \frac{|S^\pi(i)|}{|S^A(i)|}$$

$S^\pi(i) = \{s | \pi(s) = i\}$: A set of states in the LTG where i is the converse policy action.

$S^A(i) = \{s | i \in A_s\}$ (where A_s is a set of actions available from state s): A set of states where the instructional component i was taken.

$|X|$: Number of elements in X

Also notice that $S^\pi(i) \subset S^A(i)$.

We then tested if there was a significant difference in the mean normalized frequencies between effective and ineffective instructional components. Table 3 shows the mean normalized frequencies of ineffective and effective instructional components and those standard deviations. The effect size is a ratio of the difference between two means to the standard deviation. Table 3 suggests that regardless of the quality and contrast, ineffective instructional components were selected as a converse policy action notably many times more than effective ones. The differences were all statistically significant using t-test ($p < 0.01$). The data also suggest that the difference in the frequencies between ineffective and effective components becomes the smallest (as indicated by the smallest effect size) when contrast is small and quality is high, as we expected.

These results support the hypothesis that *relatively ineffective instructional components tend to appear in a converse policy action set more frequently than effective instructional components. It is also shown that the converse policy is robust enough to discriminate the effectiveness of the instructional component regardless of the quality (operationalized as the ratio of effective vs. ineffective components) and the contrasts (operationalized as the difference in the growth of logit between effective and ineffective components).*

Table 3: Comparison of the mean normalized frequency between ineffective (Inef.) and effective (Ef.) instructional components. A number in the parentheses shows an effect size.

Quality	Contrast					
	Large		Moderate		Small	
	Inef.	Ef.	Inef.	Ef.	Inef.	Ef.
High	0.7±0.2 (4.0)	0.2±0.1	0.7±0.1 (5.7)	0.1±0.1	0.5±0.1 (3.1)	0.2±0.1
Med.	0.4±0.1 (7.9)	0.1±0.05	0.4±0.1 (8.5)	0.1±0.04	0.4±0.1 (3.6)	0.2±0.1
Low	0.4±0.1 (9.2)	0.04±0.04	0.4±0.1 (10.0)	0.04±0.03	0.4±0.1 (4.5)	0.1±0.1

6.2.2 Accuracy of recommendation

We next evaluate the precision and recall scores of recommendations created by frequency heuristic to answer RQ2: How accurately does the frequency heuristic compose a recommendation?

To compose a recommendation, we need to define a cut-off value. As a reminder, those instructional components whose normalized frequency is more than a pre-defined cut-off are labeled as “ineffective” and included in the recommendation. What the cut-off value should be is an empirical call.

In the current study, we compared two cut-off values using mean (M) and standard deviation (SD) of the normalized frequency: M+SD vs. M-SD. To evaluate the accuracy of recommendation, we computed Precision and Recall as follows:

$$Precision = \frac{|\Phi_{ineff}^R|}{|\Phi^R|}$$

$$Recall = \frac{|\Phi_{ineff}^R|}{|\Phi_{ineff}|}$$

$$F1 = 2 * \frac{Precision * Recall}{Precision + Recall}$$

$|\Phi_{ineff}^R|$: Number of *ineffective* instructional components included in a recommendation

$|\Phi^R|$: Number of total instructional components included in a recommendation

$|\Phi_{ineff}|$: Number of *ineffective* instructional components in courseware

We investigated how precision and recall scores vary depending on the cut-off and the condition of the learning data (contrast, quality). Figure 2 shows precision and recall scores comparing M-SD and M+SD cut-offs for each quality of the courseware. For each data point, three levels of contrasts are aggregated, because there was no notable difference among them. The figure show that when the quality of courseware is low to medium, the M-SD cut-off had better recall and precision scores than M+SD. F1 score for M-SD was 0.99 and 0.92 for low and medium qualities respectively. On the other hand, when the quality is high, the M+SD cut-off outperformed M-SD. F1 scores of M+SD for high quality courseware was 0.88.

In sum, the frequency heuristic adequately works to determine which instructional components must be taken into a recommendation for courseware refinement. In the current simulation study, over 90% of ineffective instructional components

Figure 2 : Precision and recall of a recommendation. The X-axis represents the quality of the courseware. Red dashed lines show results from M+SD and blue solid lines show M-SD.

were correctly taken into a recommendation when an appropriate cut-off was used based on the maturity of the courseware. When the courseware is newly built (which is usually in a low to medium quality), the M-SD cut-off should be used, whereas the M+SD cut-off should be used for matured (high-quality) courseware. In the current study, even with the high-quality courseware where only 10-20% of all instructional components in the courseware are ineffective, RAFINE was able to correctly include ineffective components in the recommendation with the M+SD cut-off.

7. DISCUSSION AND LIMITATIONS

In the evaluation study, we had two research questions. RQ1: How robust is the converse policy as a detector for relatively ineffective instructional components against different conditions of learning data? RQ2: How accurately does the frequency heuristic compose a recommendation?

First, the comparison of the normalized frequency revealed that relatively ineffective instructional components tend to appear in a policy action set significantly more frequently than effective ones regardless of the contrast and the quality of courseware. This suggests that the converse policy as a detector for relatively ineffective instructional components is robust enough against different conditions of learning data (RQ1)

Second, we evaluated the accuracy of the recommendation created by the frequency heuristic to answer RQ2. The results showed that when we use a different cut-off depending on the maturity of courseware, the recommendation created by the frequency heuristic accurately includes ineffective instructional components.

The results from the evaluation study showed that RAFINE can find deficits of the existing courseware by analyzing learning trajectory data on behalf of human experts. Although videos, quizzes and hints are evaluated in the evaluation study, RAFINE could also analyze other types of instructional components such like written paragraphs, tables, figures, etc. However, accurately tracking how students review these instructional components while learning is not straightforward—e.g., the ordinal clickstream data do not convey whether a student was reading a text instruction or not.

One limitation of this study is that there are several assumptions about learning trajectory data. First, we assume the presence of the KC model. Instructional components should be tagged with a KC to apply the RAFINE method. Therefore, the recommendation created by RAFINE changes depending on a KC model. Methods to build a good cognitive model that captures the fine KC model are studied as mentioned in the related works.

Second, we also assume that the students' mastery level is measured correctly. Since the reward function depends on the change of mastery level from the current state to the next state, it is essential that the measured mastery level is not far from the actual level of students' understanding on a skill.

Third, variations in the learning trajectory graph are critical when applying the RAFINE method. To get better performance, RAFINE must be fed a learning trajectory graph that contains diverse learning activities. If there is only one path in a learning trajectory graph, for example, the converse policy has no choice but to select an instructional component that appears in the path as a converse policy action.

One question that is not addressed in the current study is about the students' differences—how much the students' individual differences affect the “effectiveness” of each instructional component. Instructional components that are quite effective for one group of students may not be as effective for another group of students. Although it is out of the scope of the current paper, we have two working hypotheses for future studies. One hypothesis is about the majority rule—the big data overrides the individual human factors and detects the latent trends. Another hypothesis is about the individualized student model—entering individual student factors into the student model used to compute the mastery level, e.g., the individualized additive factor model [24]. Further studies will be necessary to address these issues in detail.

8. CONCLUSION

We found that the RAFINE method could serve as a building block for the evidence-based, human-in-the-loop, iterative online courseware learning engineering method by detecting the deficits of the courseware. RAFINE analyzes learning trajectory data collected from existing online courseware using the reinforcement learning technique and identifies ineffective instructional components. The detected components are provided to courseware developers as a recommendation for refinement. Given the recommendation, courseware developers can efficiently improve the courseware by modifying the listed instructional components.

In addition to providing a new evidence-based learning engineering method, we also proposed a technique called the *frequency heuristic* and contributed to the community of applications of reinforcement learning (RL). The frequency heuristic is a novel way of interpreting the policy for evaluating the actions in MDP. It operates differently from the conventional applications of RL in which the policy is used for optimization. In RAFINE, the frequency heuristic is applied to the converse policy to detect ineffective instructional components (i.e., action) that had relatively less contribution to learning. In the evaluation study, we demonstrated that the frequency heuristic over the converse policy is potentially a powerful analytic tool to detect a relative weakness among available actions.

For future studies, it is crucial to measure the actual effectiveness of the proposed method in authentic learning settings and apply the method to real students' learning data.

Recommending Remedial Readings Using Student Knowledge State

ABSTRACT

Assessment plays a vital role in learning, as it provides both instructors and students with feedback on the overall effectiveness of their teaching or learning. However, when a student fails to correctly answer certain questions in an assessment (such as a quiz), the student needs specific recommendations that are tailored to their learning needs and to the knowledge deficiency exposed by the assessment outcomes. In this paper, we explore the methods for automatically identifying the recommended textbook materials that are most relevant and suitable to the student. In particular, we conducted experiments on how to incorporate students' current knowledge state on domain concepts associated with the activity to recommend personalized remedial sections to each student. The results show that incorporating student knowledge states can significantly improve the quality of recommendations as compared to traditional content-based recommendations.

Keywords

Remedial Recommendation, student Modeling, domain concepts, dynamic student knowledge

1. INTRODUCTION

Along with the rapid development of internet and communication technologies, as well as the increasing amount of online materials in diverse formats, online learning and its supporting platforms have become vital for learning various new subjects. Regardless of if it is a self-regulated platform or instructor-regulated platform, learners are provided with diverse types of content, which may include notes, textbooks, videos, and other lecture material. Similar to traditional learning, in order to evaluate a learner's progress through course materials, various forms of assessments are embedded in the online learning process. For example, course platforms integrate quizzes and exams at the end of each learning module (section, subsection, or part). This is particularly important in self-regulated online courses, since these assessments

help learners to reflect on the content and estimate their learning progress. A complete learning loop should incorporate the provision of providing learners' relevant remedial content materials to compensate for the knowledge deficit exposed by the assessment. In classic computer-assisted instruction (CAI), where the course content and assessments were created either by the same author or by a team, links to remedial content were created manually. However, modern online learning extensively uses open educational resources and question banks created by many independent authors. In this context, an automatically generated remedial recommendation of learning content after a failed assessment is vital to the success of online learning.

A natural approach for an educational recommender system is to use content similarity as the basis for remedial recommendation [36]. This approach recommends remedial content that is similar to the assessed content. However, deficiencies in student knowledge that are exposed by the assessment might not be limited to the most similar content. Thus, a content similarity-based approach could lead to a recommendation of materials that have either already been mastered by the student, or a recommendation of material for which students lack the prerequisite knowledge.

Q: A person searches for "Michael Jordan sport" in google search engine. Please mark all the possible information needs of the person:

- A.** A person who is part of some sport
- B.** A sport named Michael Jordan
- C.** Michael from country Jordan

Figure 1: Quiz example

The goal of this study is to explore the method of remedial recommendation that dynamically address student needs. The proposed approach is to focus on modeling the domain-relevant concepts that the student is learning. The motivation for using domain-specific concepts in representing recommended documents is illustrated by Figure 1. The figure shows an example question from the "information retrieval" course. A term-based recommendation (keyword-

"Recommending Remedial Readings Using Student's Knowledge state" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 233 - 244

based) could count repeated words in the question and bring up documents related to “Michael Jordan” or “Sport”. However, these documents may be irrelevant and thus would not be helpful for remediation. In contrast, a recommendation algorithm that attends to domain-specific concepts would select documents that are related to “Google search engine” or “information need”, which can cause the recommended documents to be more directly relevant to the knowledge assessed in the question.

We believe that a beneficial remedial recommendation also needs to dynamically model the student’s knowledge of the domain-specific concepts. A content-based or domain concept-based static remedial recommendation would provide the same recommendation to different students, regardless of the individual students’ different levels of knowledge deficiency exposed by the assessment outcomes. For instance, still considering the example in Figure 1, students who are already familiar with the concept of “search engine” but are struggling with the concept of “information need” would need different remedial recommendations than those who are struggling with the concept of “search engine”.

As a result, in this paper we will investigate the effects of incorporating both domain knowledge and student knowledge in remedial recommendations. More specifically, we aim to address the following research questions:

- **RQ 1:** Does the domain-based representation of educational content help perform remedial recommendation, either by acting alone or in combination with the content-based recommendation?
- **RQ 2:** Can we use automated keyphrase extraction techniques to generate domain-based representation?
- **RQ 3:** Does the augmentation of student knowledge on domain-based recommendation help in providing dynamic remedial recommendations?

To address the research questions, we proposed a concept-level static remedial recommendation (StatRemRec) and a knowledge-level dynamic remedial recommendation (DynRemRec). To conduct this research, we used an online reading platform (ReadingCircle) [13]. The system provided the students with a platform to read their course textbook. In ReadingCircle, every subsection contains a quiz to test student performance (for details 4.1). Data obtained from the ReadingCircle platform was used to investigate and evaluate the proposed recommendation approach. We hypothesize that the StatRemRec and DynRemRec approaches will provide better recommendations than state-of-the-art recommendation models that completely ignore both the domain and student dynamic knowledge states.

We also released a dataset of annotated questions in our existing online textbook with relevant sections. This data can work as a benchmark for content recommendation and linking task¹. The code and student model are available at: <https://github.com/khushsi/RemRec>

2. RELATED WORK

Despite their overall similarity, the roots of both static and dynamic remedial recommendation approaches can be traced to two different research areas. The *static recommendation* of educational resources does not depend on the state of an individual student, and as a result, can be generated before a student starts working with learning content. Historically, static recommendations were explored in the field of educational hypermedia and called “intelligent hypertext”, since this approach recommended resources that were not connected by a human-authored link. Research on intelligent hypertext started in the early days of this field and originally focused on linking resources using term-based resource similarity [22, 41]. Simple keyword-based approaches have been gradually replaced by semantic-level similarity, based on concepts of semantic web and domain ontology [8, 28], and later by modern text-processing approaches, such as topic modeling and concept extraction [24, 1, 37, 14].

The emergence of MOOCs and the online accumulation of large volumes of educational content encouraged a new wave of research on “intelligent” linking focused on connecting primary learning content, such as textbooks and MOOCs, with different external learning resources, such as videos, Wikipedia pages, or research papers [1, 18, 20].

In contrast, the *dynamic recommendation* model of educational content has to be generated on the fly, based on the current knowledge or interest of the learner. Dynamic recommendations could be traced back to the classic works on adaptive course “sequencing” [23] and generation [10]. The first generation of this work focused on adaptation to student levels of knowledge and used different student modeling approaches from the field of intelligent tutoring [35]. The emergence of recommender systems encouraged a different generation of research on dynamic recommendation that focused on learner interests and used techniques from the areas of recommender systems [21]. Due to its popularity, the term “recommendation” is now used to refer to both knowledge-based and interest-based recommendations. Recent work on educational recommendation frequently combines both knowledge and interest adaptation and supports a range of needs, such as fine-grained resource recommendation for practice activities [2, 37], reading materials [29], and videos, as well as coarse-grained recommendation of courses [30, 7] or textbooks [31].

The majority of research on educational recommendation has focused on recommending students’ next thing to do and assumes that the student’s overall progress is good. A different recommendation approach, known as remedial recommendation [3], has focused on recommending resources that can help a student to learn a concept in which a student is weak, in order to improve understanding or resolve misconceptions. Konstantin et al. [4] proposed a knowledge-gap based remedial recommendation approach. The method considers learners’ previous success rates and categorize learners as expert, intermediate, or unknown. They found that this coarse-grained categorization may help in providing recommendations based on student needs. Although such a coarse-grained categorization is beneficial, it assumes that there is a single learning rate for all students. However, the existing advancement in education technologies have ways

to infer students' individualized levels of knowledge [32] and learning rates [9, 11], called student models. In our work, we used student models to define fine-grained student knowledge states and explored the possibility of using them in remedial recommendations.

3. METHODOLOGY

In this paper, we investigated the effect of dynamically incorporating domain knowledge and student knowledge for remedial recommendation. The intuition is that this dynamic incorporation can enable more relevant and suitable resources to help students recover from failure within the assessment.

3.1 Problem Description

Formally, the research problem can be described as: for a given student S , who was recently assessed on question q ; if student S failed on question q , we want to provide student S with a recommended reading from a content set $T = t_1, t_2, \dots, t_c$ to help the student to grasp the knowledge that would be required to succeed on question q .

The vector representation of texts T and question q are constructed using domain concepts, the recommendation is computed based on the cosine similarity between the vectors of text T and question q , and the top five most similar texts are selected for the recommendation.

3.2 Static Remedial Recommendation (StatRemRec)

StatRemRec targets remedial recommendation based on incorporating semantic knowledge or domain knowledge of the content. To build a domain-based representation of education material, we used domain concepts. The approach of a domain concept-based representation of education material is commonly found in intelligent tutoring systems, which focus on problem-solving support and where every practice problem is associated with a set of domain knowledge components (concepts) [17]. In our case, concepts are expressed as key phrases. Each key phrase depicts a fragment of domain knowledge, a semantic entity, or a fine-grained topic. Each target education material, textbook section, and question (in our case) are annotated with domain concepts. Figure 2 shows an example output of these annotated domain concepts mapped to both a text and a question.

Once we have obtained a domain concept for both texts and questions, we build a representation of texts and questions as a frequency-based vector representation, based on the presence of domain concepts for each text and each question. For recommending texts for a particular question, we apply cosine similarity between question q and all the available sections in the text T and rank the top five most similar texts $\{R_q^1, R_q^2, R_q^3, R_q^4, R_q^5\}$ that share the same domain concepts with the questions q .

3.3 Dynamic Remedial Recommendation (DynRemRec)

StatRemRec accounts for semantic knowledge in the document for recommending remedial materials. Although this is an improvement on a purely keyword-based content recommendation system, StatRemRec still recommends the same

content for each student, regardless of the student's real-time content requirement. For example, a student failing on a question that asks about "Multiplication" will always be given recommendations for readings related to "Multiplication" with StatRemRec. For instance, if a student's skills are weak in a prerequisite concept, e.g. "Addition", it is crucial to support that student's current needs.

In education systems, intelligent tutoring systems account for this student-specific information to provide students with adaptive practices and has been shown to help with effective and efficient learning [38]. To provide adaptation, the tutors maintain dynamically changing student knowledge states while the student uses the tutoring system.

In DynRemRec, we maintained dynamically changing student knowledge states and used students' real-time knowledge states to generate a personalized remedial recommendation for each student. The following subsections provide details about student knowledge state generation and our approaches to integrating them into our remedial recommendation.

3.3.1 Student Knowledge State Generation

For generating students' knowledge state, we used a traditional and widely accepted student modeling framework, performance factor analysis (PFA) [34]. This model relies on expert annotated *skills* (also known as knowledge components or concepts). *Skills* are knowledge units associated with student activities, steps, and questions on which students' knowledge and performance are tested [17]. In our work, we considered *domain concepts* as *skills*, which has been shown to work in previous work on student modeling in online textbooks. [40, 16, 42]. At the base of the model is a Qmatrix, a binary matrix where columns represent *concepts or skills* and rows represent questions. Each cell is a binary value, where 1 in the cell with row r and column c represents that question r is an application of concept c . PFA represents the student's probability of success in answering a question as a function of the student's previous successful and failed attempts on the *concept* associated with the question, as shown in Equation 1

$$\text{PFA: } \ln \frac{p_{sq}}{1 - p_{sq}} = \alpha_s + \sum_c \beta_c Q_{cq} + \sum_c Q_{cq} (\mu_c S_{sc} + \rho_c F_{sc}) \quad (1)$$

where, s is a student and q is a question. c is a *concept* (skill or knowledge component). α_s is a coefficient associated with learner s (regression intercept) and represents the proficiency of learner s . Q is a Qmatrix and Q_{cq} is the Qmatrix cell associated with question q and *Concept* c . β_c are coefficients associated with concept c . β_c represents the difficulty of concept c , while μ_c and ρ_c are coefficients associated with S_{sc} and F_{sc} . S_{sc} and F_{sc} are the number of success and failure attempts, respectively, of learner s on concept c . We consider PFA, as PFA provides granular evaluation based on individual students' prior success and failure on a particular skill [34].

Example Text:

[Information retrieval](#) is the activity of obtaining [information system](#) resources that are relevant to an [information need](#) from a collection of those resources. [Searches](#) can be based on full-text or other [content-based indexing](#). Information retrieval is the science of searching for information in a document, searching for documents themselves, and also searching for the [metadata](#) that describes data, and for databases of texts, images or sounds.

Example Question:

Which technique discards information while applying [compression](#)?

A) [Lossless compression](#). B) [Tiny compression](#). C) [Zip compression](#). D) [Lossy compression](#)

Figure 2: An example of domain concepts annotated to both a text and a question. This is just for example purposes and is not part of our study. The domain concepts are marked with a link

To obtain the knowledge of a student s on a concept c when the student failed on question q , we generate the probability of failure on a concept PF_{sc} . We assumed that there exists an item c annotated with concept c , and generated the probability of failure as:

$$PF_{sc} = \begin{cases} 1 - (\alpha_s + \beta_c + (\mu_c S_{sc} + \rho_c F_{sc})) & c \in q \\ 0 & c \notin q \end{cases} \quad (2)$$

where α_s is ability of student s and β_c is difficulty of concept c . S_{sc} and F_{sc} are previous success and failed attempts of student s on concept c , after the student failed on question q .

To generate the student knowledge state vector, we represented each domain concept associated with the question q with weight value PF_{sc} . The knowledge state consists of the probability of failure to make sure that a greater weight is given to domain concepts (*skills*) where the student has a high probability of failure (where they might lack sufficient knowledge). For the concepts that are not associated with question q , we made the probability to be zero, as the goal is to recommend material related to concepts that are associated with the question.

The representation of text (documents or textbook sections) is the same for both DynRemRec and StatRemRec (i.e. representation based on frequency on domain concepts, as discussed in Section 3.3). The change is in question representation, which is based on the presence of domain concepts in StatRemRec and is based on the dynamic knowledge state of domain concepts in DynRemRec.

4. EXPERIMENTS

The dataset from ReadingCircle [13] was used for exploring DynRemRec and StatRemRec. In this section, we will introduce the dataset before presenting the details of our experiments.

4.1 Student Dataset

ReadingCircle [13] is an online reading platform. It provides an online reading environment to students in a course where they read assigned textbook materials to prepare for class.

There are quizzes of questions embedded in each section of the assigned readings to assess the progress of student learning on the content.

ReadingCircle keeps extensive logs for events associated with student reading and assessment. The dataset used in the experiments is collected from a version of ReadingCircle that has been adapted for supporting a graduate-level course on information retrieval at an University of Pittsburgh in spring 2016. There was no restriction on the number of attempts to the questions. ReadingCircle logs each and every attempt made by the student. This data set contains 9006 quiz interactions from 22 students and 4273 interactions of student failure on quizzes (for more details, refer to Table 1). The student dataset can be obtained from Datashop².

Table 1: ReadingCircle data details

Number of documents (sections)	66
Number of questions	89
Number of students	22
Average per student questions attempted	91
Student practice interactions	9006
Number of failure interactions	4273

4.1.1 Ground Truth

To evaluate the effect of recommendations on questions, we require a mapping of questions to sections. Each question maps to the section where it appears. This assumption holds as each quiz is created by subject experts (instructors and teaching assistants) to assess student knowledge in a particular section. In a few cases, a quiz will assess multiple sections. In this case, we map the questions appearing in those quiz to multiple sections. For more details on the question-to-section mapping dataset, please refer to Table 2

Table 2: Ground truth for recommendation

Number of (sections)	66
Number of questions	89
Number of questions per section	1.93
Number of questions linked to single section	81
Number of questions linked to multiple sections	8

²<https://pslcdatashop.web.cmu.edu/Project?id=637>

4.2 Domain Concept

Concept-based textbook representation was introduced by early projects that focused on adaptive textbooks [15, 43]. Adaptive textbooks associated every section of a digital textbook with a set of domain concepts (called outcomes) that are present in that section. In this work, we investigated both expert-annotated *domain concepts* [42] and automated extracted *domain concepts* [26, 6, 25].

- **Expert-based concepts (EBC):** For EBC, we used concepts that were generated by Wang et al [42]. Wang et al. [42] developed comprehensive expert-based annotation rules and proposed a two-step concept annotation system with three subject experts. [42]. The concepts are available for sections in the “Introduction of Information Retrieval” book, which is the same book that students are reading in the online course in ReadingCircle.

In order to conduct the experiment, we want both questions and the text that are associated with the concepts. However, EBC is only available for textbook sections. In order to associate concepts with questions, we created a list of domain concepts using concepts in all sections, and performed a simple lookup on the concept list to find the domain concepts in the question and answer text. More details about the EBC concepts is mentioned in Table 3.

Table 3: EBC Concepts

Number of unique concepts	1047
Average number of concepts per section	30.83
Average number of concepts per quiz	6.52

To check if questions have concepts only from related sections, we plotted the distribution that depicts the number of unique sections that share concepts with questions, as shown in Figure 3. These statistics show that questions share concepts with an average of 24.3 sections.

Figure 3: Distribution of number of unique sections sharing domain concepts per question.

- **Automated concept extraction (ACE):**

StatRemRec and DynRemRec represent text with concept-level representation. In the case of DynRemRec, the student model is also trained using concepts associated with student practice activities. However, traditional expert-based concept generation is time consuming and hard to obtain with the incorporation of open-source course materials. Hence, it is impractical if time-consuming expert concepts becomes a necessary step in student recommendation on education resources. To prove the ease of incorporating StatRemRec and DynRemRec, we dedicated this set of experiments to test the feasibility of concept-level remedial recommendations (RQ 2). The experiment was designed to test StatRemRec and DynRemRec on concepts that were automatically extracted through keyphrase extraction techniques [6, 25, 26]. It is debatable if keyphrase extraction techniques extract domain concepts and could be used as knowledge components or *skills* on which students’ knowledge is measured. For evidence of using concepts as *skills*, we relied on evidence from work by Thaker et al. [40] and Huang et al. [16], in which student models are trained on keyphrases in education content for adaptive textbooks.

To perform the experiment and explore research question RQ-2, we selected three state-of-the-art keyphrase extraction techniques, as discussed below:

1. TextRank: TextRank [26] is a classic unsupervised keyphrase extraction technique. TextRank converts each document into a graph of words, based on word co-occurrence criteria. The algorithm then applies the page rank algorithm to the graph and extracts the important keyphrases.
2. CopyRNN: CopyRNN [25] is a supervised deep-learning based sequence-to-sequence keyphrase generation technique. CopyRNN is one of the state-of-the-art supervised keyphrase extraction techniques. This will help us evaluate our model for supervised keyphrase extraction.
3. TopicRank: TopicRank [6] is a graph-based unsupervised keyphrase extraction technique. The difference is TopicRank focuses on finding keyphrases that belong to the topic of the document. As a result, this technique can provide more insight into topic-based concept extraction.

Table 4 shows more details of the concepts extracted by different ACE methods. The table indicates that different algorithms will choose a different domain space for representing the domain.

4.3 Term-Based Recommendation Baseline (TextRec)

For our baseline, we used a simple term-based recommendation approach. TextRec finds the similarity between two documents (section text and quiz text) based on words that are present in the text. Each term in the document is used as a semantic unit and the document is represented as a vector of the TF-IDF weights [39]. Such a TF-IDF based document similarity was recently found to be effective for

Table 4: Statistics of ACE datasets

Model	Average no of Concepts Section	Quiz	Unique Concepts	Overlap Sections
CopyRNN	14.56	2.32	558	2.29
TextRank	27.39	7.53	698	28.88
TopicRank	96.01	7.85	2469	32.94

finding similar education resources [37]. Although state-of-the-art recommendation techniques use advanced semantic representations that use both word and document embeddings [27], we did not explore much in this area, as our focus is in understanding the effectiveness of including domain and student knowledge in recommending remedial resources.

4.4 Experiment Steps

To address the research questions mentioned in Section 1, we conducted the following experiments:

1. **Term vs Concept Representation:** To understand if domain-based representation is effective (RQ 1), we compared the concept-level techniques of StatRemRec and DynRemRec to the term-based approach TextRec.
2. **Fusion experiment:** As the TextRec approach has a term-based representation of education material, while StatRemRec and DynRemRec use concept-level representation, to leverage both types of representation (RQ 1), we fused the term-based approach with domain concept-based approaches. The fusion of term-based methods with concept-based methods is done by simple linear interpolation, as specified in Equation 3

$$Sim_{q_i, t_j}^{fused} = \alpha \cdot Sim_{q_i, t_j}^{concept} + (1 - \alpha) \cdot Sim_{q_i, t_j}^{text} \quad (3)$$

where Sim_{q_i, t_j} is the similarity between question q_i and section t_j . To determine the interpolation coefficient α in Equation 3, we selected the α that gave the best result for *TextRec + StatRemRec* on expert-based concepts and used it in all of our experiments.

3. **Experiment with ACE:** To address research question RQ 2, we performed remedial recommendation by using keyphrases as domain concepts.
4. **Knowledge Augmentation:** To address research question RQ 3, this experiment investigated differences in the recommendations generated from both StatRemRec and DynRemRec.

Figure 4 provides a complete picture of the experiment set up with all of the resources that were used for the experiment. Student interaction data is divided into students stratified in ten random folds. The training folds are used for training the student model, with available concept indexing for each question. The recommendation is evaluated on the test fold. The student model is used to generate dynamic knowledge-based concept representations for DynRemRec, and the results reported in Section 5 are averaged over 10 test folds.

4.5 Evaluation Metric

As discussed in Section 4.1.1, the question to section mapping is one to many, so we adopted mean reciprocal rank (MRR) and mean average precision (MAP) to evaluate the recommendations [33]. MRR is a good metric to understand, on average, the position on which a relevant recommendation is obtained, and MAP@5 will generally prefer the algorithm that recommends more relevant sections at the top of the list. Here, the wrong recommended section is considered not to be relevant and the correct section is considered to be relevant.

5. RESULTS AND DISCUSSION

5.1 Term vs Concept-Based Recommendation

Table 5 shows the performance of the term-based approach TextRec the and domain concept-based approaches StatRemRec and DynRemRec. Both StatRemRec and DynRemRec performed lower than the baseline TextRec. One potential reason for this finding is that TextRec relies on the keywords from the whole content of both the quiz and the section, while both StatRemRec and DynRemRec only index based on a small number of identified concepts. Based on our calculation, the average length of sections in our dataset is 1,345 words, whereas the average number of concepts annotated by experts in each section is only 13.5, which indicates that the concept-based representation relies on a comparatively few number of concepts.

These results show that, despite the importance of domain-specific concepts in explaining the content in education, confining the representation of text with only concept-level content could cause too much loss in useful textbook content.

5.2 Fusing Term and Concept-Based Recommendations

As Meng et al. [24] pointed out, term-based content representations of education materials can provide fine-grained term level information and statistics, while concept-based representation works on both a coarse-grained topic and semantic level. Consequently, it is beneficial to have information from both these representations when recommending a relevant document to a student. As term-based representation identifies the content similarity based on shared terms, concept-level representation provides emphasis on semantics and the knowledge that is represented by the concepts. To leverage the combined power of these two representations, we conducted fusion experiments on both the term- and concept-level approaches, as mentioned in Section 4.4. As Table 5 shows, there is a clear indication that fusion (*TextRec + StatRemRec*) surpasses the baseline TextRec and benefits from concept-level representation. To investigate this effect in detail, we plotted the performance of StatRem-

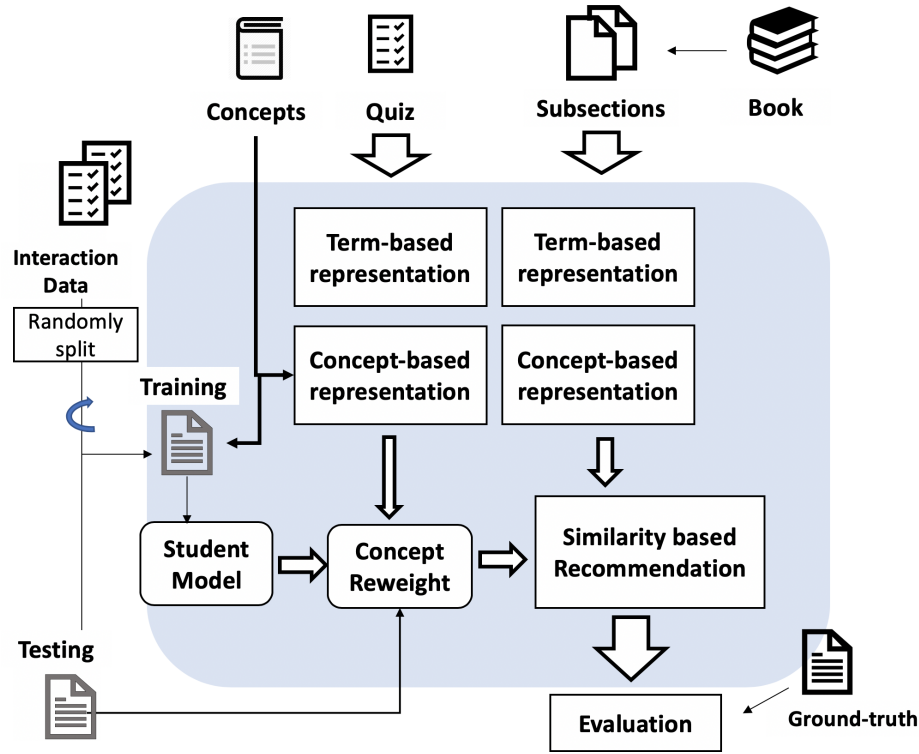

Figure 4: Experiment Setup

Table 5: Remedial recommendation performance on failed questions in ReadingCircle system in terms of MRR. * denotes a significant performance change of *metric* over text-based recommendation TextRec using a non-parametric Wilcoxon signed rank test. Numbers shown in bold indicate the top two best performance. The performance is based on expert annotated EBC. Parameter α for *TextRec + StatRemRec* and *TextRec + DynRemRec* is 0.60 based on *MAP@5*

Model	student knowledge	MRR	MAP@5
TextRec	-	83.00	74.01
StatRemRec	-	73.47	68.40
DynRemRec	✓	71.05	66.06
TextRec + StatRemRec	-	*91.01	*86.18
TextRec + DynRemRec	✓	*89.53	*83.90

Rec for different values of the interpolation co-efficient α , as shown in Figure 6.

Figure 6 and Figure 5 display some important characteristics of these recommendations. The curve of *TextRec + StatRemRec* starts with the performance of TextRec at the value of $\alpha = 0$. Initially, along with α increases from $\alpha = 0$ to $\alpha = 0.3$, the performance of the fusion-based approach *TextRec + StatRemRec* increases both in MRR and MAP@5, which shows the benefit from the inclusion of concept-based representation. Next, MRR performance stabilizes for a period from $\alpha = 0.3$ to $\alpha = 0.6$, which shows no obvious change in the position of the top-ranked relevant documents in rank lists. In this interval, MAP@5 (Figure 6) keeps increasing, which shows that concept-level representation are helping in either recommending new relevant documents or bringing already ranked relevant documents up at a higher

ranked position. The performance of MAP, which looks at all the recommendations, is best at $\alpha = 0.60$. Since the performance improvement comes with the increasing weight on StatRemRec, it provides evidence that recommendation benefits more from the domain-specific concept-based representation. Fusion improved the performance of recommendation by 16% (significantly, with significance tested using Wilcoxon signed rank test), providing an answer to our research question RQ 1 that StatRemRec improves recommendation quality when augmented with a traditional content-based recommendation system.

5.3 Performance with ACE

In research question RQ 2, the goal is to understand the feasibility of using ACE as a domain concept and to use it in providing remedial recommendations. Table 6 compares the performance of some traditional ACE techniques.

Figure 5: Threshold based recommendation values in terms of MAP with change in α values

We experimented with both supervised and unsupervised keyphrase extraction techniques. It is apparent from the performance of ACE that these techniques beat traditional content-based recommendation systems. TextRank does not improve much on content-based recommendation, but both TopicRank and CopyRNN surpass content-based recommendation. TopicRank is a winner among three methods and beats the recommendations that are based on EBC. A possible reason could be the difference between keyphrase extraction methods. TextRank and CopyRNN focus on extracting important keyphrases from a document, while TopicRank is focused on extracting keyphrases that are related to topics discussed in a document. Thus keyphrase extracted by TopicRank is more analogous to concepts discussed in the course. We experimented with comparatively few and somewhat simple keyphrase extraction techniques, as we aim to provide a piece of simple evidence for the feasibility of our approach (RQ 2). We leave for future work to perform a more comprehensive experiment with automated concept extraction, which extracts more advance domain knowledge like prerequisites and outcomes within a textbook [12, 19].

5.4 Augmenting Knowledge in Concept-Level Representation

The main goal of DynRemRec is to provide students with personalized remedial recommendations based on their real-time information needs. As Table 5 shows, DynRemRec performed worse than both TextRec and concept-based StatRemRec in MRR and MAP@5. As with StatRemRec, we fused DynRemRec with TextRec. The fusion of DynRemRec with term-based representation (TextRec + DynRemRec) revealed a similar output as TextRec + StatRemRec. This fusion improved the performance of recommendations by 13%, as compared to TextRec.

Although the fusion (TextRec + DynRemRec) improved the results in the case of DynRemRec, it is evident from Figure 6 that *TextRec + DynRemRec* was not able to improve over the performance of *TextRec + StatRemRec*. An explanation

of this output is that DynRemRec addresses the need of students at each recommendation, while StatRemRec provides the same static recommendation to each student. This means that there may be cases in which experts think that a student will benefit from reading a particular section, but actual student needs might differ. Our current gold standard is expert-based, which does not target real-time student needs.

5.4.1 Effectiveness of augmenting knowledge

The goal of DynRemRec is to tailor the recommendations to student needs. Figure 7 shows the distribution of a unique set of recommendations generated against each question by *TextRec + DynRemRec*. As presented in the distribution in Figure 7, except for 12 questions, all the questions generated more than one distinct ranked list of recommendations. The results indicate that knowledge augmentation helps in providing an adaptive recommendation.

To understand the difference between StatRemRec and DynRemRec, we further investigated the cases where the recommendation of StatRemRec was different from DynRemRec. In our online textbooks, students read one to two chapters every week. The course instructors predefined the course sequence. We divided the course sections into three categories: *previous sections*, *current sections*, and *future sections*, based on the section of the question for which a student received the remedial recommendation. Previous sections can be considered as prerequisite sections, while the current section is the one for which the student is assessed. Future sections are advanced topics in which students lack complete knowledge. Figure 8 shows the distribution of recommended sections based on the three remedial recommendation techniques of TextRec, TextRec + StatRemRec, and TextRec + DynRemRec. A good remedial recommendation algorithm will recommend resources from current sections and previous sections, as understanding concepts explained in both previous and current sections will help students to solve the failed question. As Figure 8 shows, TextRec’s recommendation is distributed in all the categories, while both TextRec + StatRemRec and TextRec + DynRemRec have

Figure 6: Threshold based recommendation metric in terms of MRR with change in α values

Table 6: Remedial recommendation performance on failed questions in an ReadingCircle system, in terms of MAP@5. The performance compares EBC with ACE-based methods for both StatRemRec and DynRemRec with an alpha value of 0.60, determined by experiment, in Figure 6. The performance is mean on 10 folds. Bold indicates the performance, which is as good as EBC.

Model	TextRec + StatRemRec	TextRec + DynRemRec
	MAP@5	MAP@5
<i>ACE</i>		
TextRank	83.14	83.97
CopyRNN	84.66	84.05
TopicRank	89.90	88.85
<i>EBC</i>	86.81	84.11

more recommendations in current sections and fewer recommendations in future sections. This result shows the clear benefit of the addition of domain knowledge, which helps in recommending the sections that are appropriate for the learner.

Augmenting student knowledge (TextRec + DynRemRec), on the other hand, further decreased the recommendation of future sections. However, DynRemRec also decreased the current section and provided more recommendations in previous sections than StatRemRec. Recommendations on previous section can be the consequence of students' knowledge state. If a student is still weak in a prerequisite concept, StatRemRec will not consider those cases, while DynRemRec, which provides adaptive remedial recommendation, will make recommendations that are based on students' needs. This gives indirect evidence about the effectiveness of augmenting student knowledge in recommending resources.

6. CONCLUSIONS AND FUTURE WORK

This paper investigated the value of using domain and student knowledge for the remedial recommendation of reading resources.

We found that the use of domain knowledge significantly improves recommendation performance when fused with traditional content-based recommendations. The model *TextRec*

+ *StatRemRec*, which augments content-based recommendation with domain concept-based recommendations, significantly outperformed the traditional content-based recommender TextRec. Currently, fusion is achieved with a simple linear interpolation; we would like to investigate other fusion techniques in future studies.

While domain knowledge improves the quality of recommendation, it doesn't account for the knowledge and needs of individual students when recommending remedial reading. To address this, we tried to use dynamic student models that represent students' current knowledge state on domain concepts for providing truly personalized recommendations. *TextRec* + *DynRemRec*, which augments student knowledge with a content-based recommender, provided evidence to support the benefits of adding students' knowledge state for an adaptive recommendation. Although we provided some preliminary evidence for a personalized recommendation, it would be necessary to conduct a comprehensive study with real-time student feedback on recommendation. In future work, we will further investigate this phenomenon by incorporating different recommendation techniques to our online course platform. Such a study will provide a more accurate evaluation based on students' learning gain and overall system usage.

To address research questions RQ 1 and RQ 3, we used

Figure 7: Distribution of unique lists of recommendations per quiz by *TextRec* + *DynRemRec*

Figure 8: Category of recommended sections. The graph only plots for top recommended section. Previous, current, and future sections are categorized according to the sequence of the course.

expert-annotated domain knowledge (EBC) for building our recommender. As expert-provided concept indexing is expensive in terms of both time and resources, we further investigated traditional concept extraction approaches, such as ACE, to make our approach more feasible in practice. The performance of domain and knowledge augmented recommender on ACE proves that the technique is easy to adapt to new course content, for which expert-based concept indexing may not be available. A good future direction for this work is to investigate the importance of ACE by incorporating advanced semantic topic modeling [5] and prerequisite extraction techniques [19, 12]. A better representation of domain knowledge can lead to a more reliable knowledge unit generation for pedagogical design.

This work represents a first exploration of the power of considering students’ knowledge state in recommending personalized remedial readings. The present work provides an interesting insight into automated remedial recommendation. We believe these types of models could play a more promi-

nent role in future models of online learning where immediate or individualized instructor feedback is not available.

ABSTRACT

Front camera data from tablets used in educational settings offer valuable clues to student behavior, attention, and affective state. Due to the camera's angle of view, the face of the student is partially occluded and skewed. This hinders the ability of experts to adequately capture the learning process and student states. In this paper, we present a pipeline and techniques for image reconstruction of front camera recordings. Our setting consists of a cheap and unobtrusive mirror construction to improve the visibility of the face. We then process the image and use neural inpainting to reconstruct missing data in the recordings. We demonstrate the applicability of our setting and processing pipeline on affective state prediction based on front camera recordings (i.e., action units, eye gaze, eye blinks, and movement) during math-solving tasks (active) and emotional stimuli from pictures (passive) shown on a tablet. We show that our setup provides comparable performance for affective state prediction to recordings taken with an external and more obtrusive GoPro camera.

Front Camera Setup, Inpainting, Affective Computing, Classification, Deep Learning

1. INTRODUCTION

Tablet computers have found quick application in education [14] as the technology offers new opportunities to students and teachers. It has been shown that tablets can influence learning pathways [19] and improve digital skills [47]. Moreover, tablets typically have built-in cameras, which can be used to unobtrusively record the student during the learning. Such data offers valuable clues to experts about the student's learning behavior and attention. Student observation has been implemented in studies with external camera setups [56]. Such frontal-view camera data can also be used for predictions of the affective states of a student based on

facial feature extraction [46], which works robustly even with low-resolution recordings [43]. Affective states are psychological constructs describing emotions (short-term) and moods (long-term) elicited by a stimulus [36, 51], and their impact on learning has attracted considerable attention in research on intelligent tutoring systems and education [3, 13, 41]. For example, Craig et al. [12] have found a positive correlation between learning and flow and a negative correlation between learning and boredom.

Using external cameras for frontal view recordings of students provides an optimal viewing angle for robust facial feature extraction and affective state prediction. However, such setups require externally positioned cameras, which can be obtrusive and further depend on timestamp synchronization with the digital learning environment. Using tablet computers for learning circumvents these problems, as the built-in camera can be leveraged and timestamps are inherently in sync. Built-in cameras have, however, a sub-optimal viewing angle, leading to partially occluded and skewed faces in the recordings that makes it difficult to robustly extract facial features for affect prediction.

In this paper, we therefore propose a camera setup for tablet computers and a deep learning-based image processing pipeline to reconstruct high-quality facial recordings of students. The setup requires a small mirror to be attached to the camera to improve the visibility of the face. Then, the image is reconstructed using a neural inpainting approach. We demonstrate the advantage of this setup and our reconstruction by an application for predicting affective states. The high quality of the reconstructed image enables facial feature extraction, such as head pose, eye gaze, and facial landmarks. We compare our method with an external camera setup (GoPro camera) and show that we can achieve a similar performance for predicting two levels (high and low) of valence and arousal for students performing active tasks, i.e., solving math tasks (up to 0.73 AUC) and students performing passive tasks, i.e., exposed to emotional stimuli from pictures (up to 0.80 AUC).

2. RELATED WORK

Inpainting. Image inpainting is an image processing method to reconstruct missing or corrupted regions of an image. Common application areas include image restoration (e.g.,

Rafael Wampfler, Andreas Emch, Barbara Solenthaler and Markus Gross "Image Reconstruction of Tablet Front Camera Recordings in Educational Settings" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 245 - 256

removing scratches and text) [34], photo-editing (e.g., object removal) [50], and image coding and transmission (e.g., recovering the missing blocks) [54]. In this work, we focus on the specific task of face completion. Popular non-learning based approaches applied to faces consist of patch-based methods, where image patches are copied to missing areas. Similar patches can be identified by using a face image dataset [58]. We refer to Guillemot and Le Meur [21] for a complete overview of non-learning based models.

While non-learning based methods can have difficulties to ensure consistent image structures [24, 45, 55], learning-based approaches typically generate smoother results. A popular line of learning-based methods uses generative adversarial networks (GAN) to inpaint missing regions of an image. GANs consist of a generative network to create a new image and a discriminator network to distinguish the new image from actual ground truth images. Using such a GAN approach, Malesevic et al. [37] reported a peak signal-to-noise ratio (PSNR) of up to 20.57 for inpainting missing regions in faces. A similar performance of up to 20.2 PSNR and 0.84 structural similarity (SSIM) was achieved by Li et al. [31] using an encoder-decoder network as the generator, a local and global loss function and a semantic regularization term. On the other hand, Liao et al. [32] used a collaborative model by training a GAN simultaneously on multiple tasks (i.e., face completion, landmark detection, and semantic segmentation). Using this knowledge-sharing approach, they reported a PSNR of up to 31.5 and an SSIM of 0.97 on face inpainting.

Convolutional neural networks (CNN) have been used for image inpainting as well. The encoder compresses the image with convolutional operations into a latent space, and the decoder reconstructs the image from the compressed representation. Guo et al. [22] proposed an encoder-decoder network using full-resolution residual blocks. For face inpainting, they reported a PSNR of 29 and an SSIM of 0.95. On the other hand, Liu et al. [35] achieved a PSNR of 34.69 and an SSIM of 0.99 by adding a coherent semantic attention layer to the encoder. One disadvantage of this method is its long runtime of 0.82 seconds per image of size 256×256 rendering this method inapplicable for real-time video processing with more than one frame per second. Another problem with existing CNN-based methods is that the convolution operations are applied both to the valid and missing pixels at the same time, which can lead to visual artifacts (e.g., color discrepancy and blurriness). To overcome this issue, Liu et al. [34] proposed partial convolutions, where the convolution operations are only applied to valid pixels by masking regions that need to be inpainted. The mask is updated during training of the network, including newly inpainted values. The authors demonstrated that the approach could produce semantically meaningful predictions also for inpainting regions with different shapes and sizes, achieving a PSNR of up to 34.34 and an SSIM of up to 0.95. We use this partial convolution approach to inpaint missing regions in images from front camera recordings. The dataset used for training the network is tailored to our use case.

Affective State Prediction. In our work, we focus on the prediction of affective states in the educational domain, such as in classroom settings and online courses. It was shown that affective states have an impact on learning gain in general,

and during math learning in particular [29, 44]. For example, Csikszentmihalyi [13] showed that engaged concentration has a positive effect on learning, while boredom negatively influences learning. Affective states are often grouped into basic emotions identified by Ekman [16] (i.e., anger, disgust, fear, happiness, sadness, and surprise) or described by the valence and arousal dimensions [40]. Valence indicates if an emotion is perceived as positive or negative, and arousal represents the intensity of an emotion.

Different modalities have been used to predict affective states using the valence-arousal space in educational settings. Acoustic features from student voices during interaction with tutors have been used to predict three levels of valence [33]. On the other hand, bio-sensors (i.e., skin conductance, heart rate, and skin temperature) and handwriting data have been successfully used to predict affective states in the valence-arousal space during math solving tasks [53]. Another line of research predicted valence and arousal using mouse and keyboard interaction data collected during text writing [49]. Multi-modal approaches fusing different modalities have also been introduced for the prediction of affective states. We refer to D’Mello et al. [15] that provides a concise overview of such methods.

Prediction of affective states from video recordings is one of the most popular approaches nowadays as it allows different features to be exploited, such as body language and posture, head movement, eye gaze and facial expressions [57]. Bosch et al. [6] calculated statistics (i.e., maximum, median and standard deviation) of the frame-level likelihood values of 19 different action units (AU) (i.e., facial muscle movements), the head position and gross body movement from webcam video recordings of students playing an educational physics game. They predicted two levels of boredom (0.61 AUC), confusion (0.65 AUC), delight (0.87 AUC), engagement (0.68 AUC) and frustration (0.63 AUC). Based on this work, Kai et al. [26] found that an interaction-based model using timing and counting-based features performs worse than the video-based model. Similarly, using a math tutor, Arroyo et al. [2] found facial expressions to be more predictive for confidence, frustration, excitement, and interest than conductance bracelets, pressure mice, and a posture analysis seat. Also in other domains facial expressions have found to be a good predictor for affective states. In text comprehension tasks, confusion (0.64 AUC), engagement (0.55 AUC), and frustration (0.61 AUC) have been successfully predicted using 20 different AUs [11]. On the other hand, Grafsgaard et al. [20] found upper face movements predictive for engagement, frustration, and learning in a setting consisting of a programming tutor and a webcam. Finally, based on eye gaze features (e.g., fixation and view angle) extracted from a specialized eye capturing device, boredom (69%) and curiosity (73%) have been successfully predicted on two levels each [25]. A survey of different video-based approaches for predicting affective states is provided by Zeng et al. [57].

A majority of the existing vision-based approaches use external devices, such as webcams, and rely on posed facial expressions to predict basic emotions [57]. In contrast, we present a novel setup for reliably recording the face of users based on the front camera of tablet computers only, and hence without the need for expensive devices or synchroniza-

tion between the devices. We demonstrate the usefulness of our setting by predicting affective states in terms of valence and arousal using data from an experiment containing spontaneous (non-posed) facial expressions. Finally, for our vision-based model, we fuse different existing approaches with novel features.

3. CAMERA SETUP

We present a low-cost hardware setup for recordings from the integrated front camera of a tablet computer, maximizing the visibility of the face of the users. Videos and images captured by the front camera are preprocessed, and missing parts are inpainted using a deep learning model to reconstruct the face of the users. Our approach is image-based and processes captured videos frame by frame.

3.1 Hardware Setup

While working on a tablet (e.g., writing with a stylus) it is convenient to have the device lying on the table (see Figure 1a). Due to the field of view of the front camera, only part of a users' face is visible. To adjust the field of view of the front camera, we attached a circular mirror (3cm radius) to the tablet using a hinge (see Figure 1b). The hinge was fixed with glue so that the mirror would remain in a stable position. The mirror was mounted with an angle of 75 degrees relative to the tablet. This angle was chosen so that the visibility of the face was maximized. Due to the mirror setup, the upper part of the recordings is mirror-inverted (see Figure 1c). Depending on the conditions of the illumination of the recording environment, the exposure time of the camera of the recording device (e.g., tablet) needs to be adapted accordingly so that the camera focuses on the face instead of the background. This adjustment of the exposure time can lead to an overexposed background (see Figure 1c).

3.2 Image Processing Pipeline

A raw image captured by the front camera is split by the mirror into two parts with the upper part of the image being mirror-inverted (see Figure 2A). To reconstruct the image, we propose a series of processing steps applied to the image (i.e., flattening the splitting boundary, face composition, image rotation, and extracting the face area). Image rotation and extraction of the face area are conducted as a preprocessing step for inpainting. Further, to train our inpainting model at a later stage, we assume that we have access to a dataset Ψ of square-shaped face images.

Splitting boundary. We apply a transformation to flatten the splitting boundary of the image (green line in Figure 2A), which simplifies image processing in the later stages and improves the final results qualitatively. We divide the image into 16 rectangles with equal width. An example of such a rectangle is shown in purple in Figure 2A. For each such rectangle, we transform the region defined by the vertices p_1, p_2, p_3 , and p_4 into the region defined by the vertices p_1, p_2, p_5 , and p_6 using a perspective transformation with linear interpolation. The location of these points can be calculated beforehand (or read from the image) because the mirror remains in a fixed position. The result of the transformation is shown in Figure 2B, where the splitting boundary (green) is a straight line.

Face composition. We rearrange the image by moving the part below the splitting boundary to the top and the flipped upper part to the bottom (see Figure 2C). The cut line defined by the mirror is shown in black. In addition, we adapt the height of this cut line because depending on the distance of the face, the missing part is increasing (increasing distance) or decreasing (decreasing distance). As a next step, we push the bottom corner of the upper face towards the middle by applying a second perspective transformation to the image so that the upper and lower part of the face are matching (see Figure 2D).

Image rotation. We then rotate the front camera image so that the eyes are horizontally aligned (see Figure 2E). Using dlib [28], we extract the coordinates of the facial landmarks belonging to the left and right eye. From these landmarks, we calculate the position of the center of each eye and rotate the image around the midpoint between the eye centers so that the line connecting the center of the eyes is horizontally aligned.

Face area. We extract the face area by computing a square bounding box encompassing the face (see the orange box in Figure 2E). This bounding box is defined by the vertices $p_7 = (x_7, y_7)$ and $p_8 = (x_8, y_8)$ and is given by

$$x_7 = c_{x,I} - \frac{w_{I_\Psi}}{2} * \frac{\delta_I}{\delta_{I_\Psi}} \quad (1)$$

$$x_8 = c_{x,I} + \frac{w_{I_\Psi}}{2} * \frac{\delta_I}{\delta_{I_\Psi}} \quad (2)$$

$$y_7 = c_{y,I} - \frac{c_{y,I_\Psi}}{h_{I_\Psi}} * (x_8 - x_7) \quad (3)$$

$$y_8 = c_{y,I} + \frac{h_I - c_{y,I_\Psi}}{h_{I_\Psi}} * (x_8 - x_7), \quad (4)$$

where I and I_Ψ denote an image of the front camera and an image in the dataset Ψ , respectively. The width and height in pixels of an image are given by w and h . The x - and y -coordinate of the midpoint between the left and right eye are denoted by c_x and c_y , respectively, and δ is the distance between the eyes. Here, we assume that the origin is located at the top left of the image.

The part of the front camera image I outlined by the orange bounding box is then resized to the resolution $w_{I_\Psi} \times h_{I_\Psi}$ using bilinear interpolation. If the head of the user is close to the mirror, the face covers the full height of the image, and the bounding box might go over the upper and/or lower image borders. In such a case, we fill the parts overlapping the image with black pixels to get consistently sized bounding boxes (note that for visualization purpose only, the orange box in Figure 2E does not reflect this but instead is cut at the image border). We use the face detector of dlib [28] to test if a face and hence the landmarks of the eyes are identified in the image. In cases where the face cannot be detected, we use the landmarks of the eyes of the last image where the face could be identified (assuming that we have a video recording available, i.e., a series of images).

Inpainting missing area. As the last step in our image preprocessing pipeline, we inpaint the missing parts in the bounding box of the image (black region of the orange box in Figure 2E) with the neural inpainting approach of Liu

a) Experimental setup

b) Camera setup

c) Front camera recordings

Figure 1: The hardware setup. A user is working on the tablet (a). A mirror is attached to the tablet using a hinge (b). Due to the mirror reflections, the field of view of the front camera is changed so that the face of the participant is visible (c).

et al. [34] described in Section 3.3. We apply the neural inpainting only to the bounding box because it contains the important parts of the face (i.e., eyebrows, eyes, and mouth). We inpaint other parts of the image outside the bounding box using a simple Navier-Stokes based inpainting method provided by OpenCV [8] which is based on a circular neighborhood of three pixels for each inpainted pixel. Finally, we rotate the image back to its original orientation. This then leads to the final reconstructed image shown in Figure 2F.

3.3 Neural Inpainting

For the neural inpainting approach, we use the dataset Ψ of square-shaped face images with customized missing regions tailored to our application of tablet front camera recordings and then train the network on this dataset.

Training dataset. The model is trained on a large corpus of images from the dataset Ψ together with a mask for each image indicating the missing parts (a mask is a matrix with the same size as the image having a '1' entry for missing pixels and a '0' entry otherwise). We create the corresponding mask randomly and similar in shape (rectangle) to the expected mask in our front camera recordings (see Figure 3 for an example of two such masks applied to two images from the CelebA-HQ dataset [27]). Note that the mask (missing image region) is not necessarily horizontal but rotates if a user is rotating the tablet or the head (vertical in the extreme).

Inpainting method. Liu et al. [34] use a neural network that consists of an encoder E and a decoder D . The encoder network transforms the input image $\mathbf{I} \in \mathbb{R}^{M \times N}$ into a low-dimensional (latent) space $\mathbf{z} = E(\mathbf{I})$. The decoder then reconstructs the original image based on this low-dimensional representation $\hat{\mathbf{I}} = D(\mathbf{z})$. The encoder and decoder networks consist of $n = 8$ partial convolutional layers denoted as E_1, \dots, E_n and D_1, \dots, D_n for the encoder and decoder networks, respectively. Before each convolution operation, the image is constrained by the mask to condition the operation on only valid pixels. The mask is updated for the next layer removing masking for pixels where the convolutional operation operated on unmasked values. In addition, each layer in the

encoder network E_i is connected to the corresponding layer in the decoder network $D_i, \forall i \in \{1 \dots n\}$ using skip links. These skip links allow for copying unmasked pixels directly from the encoder to the decoder without passing the bottleneck (latent space). To direct the training of the network towards semantically meaningful inpaintings, a combination of four loss functions is used (i.e., per-pixel loss, perceptual loss, style loss, and total variation loss). Using these loss functions smooth transitions of the predicted masked values into their neighboring pixels is also taken into account. As activation functions Rectified Linear Unit (encoder) and a leaky version of a Rectified Linear Unit (decoder) are used.

4. AFFECTIVE STATE PREDICTION

We present the prediction of affective states as an example application of our mirror setup and image processing pipeline. Our classification pipeline can be generally applied to any recordings captured with a tablet front camera or an external camera (such as a GoPro). Our method assumes that we have access to reports of affective states of users based on the circumplex model of affect [48]. The circumplex model defines affective states in a two-dimensional space spanned by valence and arousal. The classification task then amounts to preprocessing the camera recordings to adjust the brightness and the frame rate and predicting valence and arousal based on features extracted from the adjusted camera recordings. Affectiva [39] provides out of the box predictions of the basic emotions and valence based on images and video recordings. However, initial tests revealed that these predictions are not of sufficient quality when applied to our use case. Thus, we developed our own set of features incorporating some additional features not taken into account by Affectiva, such as movement and fidgeting. Moreover, by using our own extracted features, we can predict arousal in addition to valence.

4.1 Preprocessing

First, we resample the camera recordings using FFmpeg [5] to a constant frame rate close to the mean frame rate. Depending on the recording device, the frame rate can vary (e.g., the frame rate can drop due to the higher load of the

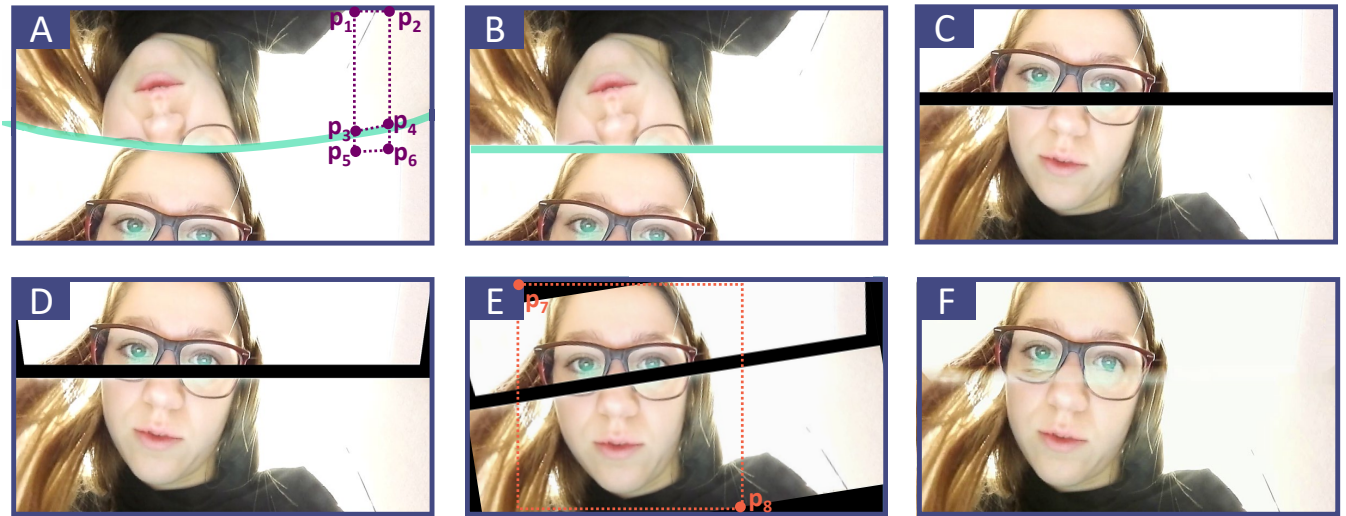

Figure 2: The main inpainting steps. The splitting boundary of front camera recordings (A) is flattened using a perspective transformation (B). The face is reconstructed from the upper and lower parts (C) and warped so that the upper and lower part match (D). Finally, after horizontally aligning the eyes (E), the missing regions (black) are inpainted (F).

Figure 3: Two example masks applied to images of the CelebA-HQ dataset [27].

device). A constant frame rate facilitates the extraction of the features and the processing of the recordings in later stages. In addition, we adjust the brightness of the recordings based on the brightness estimation of Affectiva [39] to improve the lighting of the face for the analysis. Depending on the conditions of illumination at recording time the face can be underexposed (too dark) or overexposed (too bright, e.g., when the camera is directed towards a lamp). This can hinder the accurate detection and extraction of facial features such as landmarks.

4.2 Feature Extraction

From the camera recordings, we extract several different feature types. We design all features such that they are independent of the frame rate (e.g., using percentages instead of absolute positions) to support cameras with different frame rates. To extract facial landmarks, eye gaze, and head position from the camera recordings, we rely on OpenFace [4] using static extraction (i.e., per frame without calibrating to a person). OpenFace also provides a confidence value $c(i) \in [0, 1]$ for each frame i indicating the confidence in the landmark detection estimate. If $c(i) < 0.82$, we discard the frames $i - 5, \dots, i + 5$ (i.e., 11 frames). The number of

frames to discard (11) and the threshold (0.82) were heuristically determined. All features are computed over a window containing N frames. If, after considering the confidence value, less than 80 % of the frames are remaining, we discard the window and the corresponding data point. Again, this threshold was determined heuristically. Where appropriate, we calculate for the different feature types basic statistics over the window (i.e., maximum, minimum, relative position of minimum and maximum, mean, standard deviation, and the slope of a fitted linear regression line), providing 282 features in total. In addition, to correct for differences between individuals related to facial expressions and posture, we normalize each feature according to a baseline by subtracting the feature calculated over a baseline period (e.g., watching a nature video putting the individuals in a relaxed state).

Action units. Facial action units (AUs) are based on the Facial Action Coding System (FACS) and identify independent motions of the face [17]. We extract basic statistics of the intensity (from 0 to 5) of 17 AUs covering motions in the eye, cheek, nose, mouth, and chin region. In addition, for each AU, we calculate the percentage of the presence (absent versus present) in the window. Moreover, the AUs can be directly mapped to the six basic emotions identified by Ekman [16]. Thus, for each basic emotion, we also calculate the basic statistics of the corresponding added up AUs.

Eye blinks. Researchers have found a correlation between eye blink frequency and stressful situations in a car driving simulation [23]. Similarly, a correlation between eye blinks and affective states in learning environments was found [38]. Here, we base the eye blink detection on the signal from the AU that represents eye closure as a continuous signal (from 0 to 5) with peaks indicating potential eye blinks. We detect peaks belonging to an eye blink by thresholding the signal according to the ratio between the prominence (how much a peak stands out measured as the vertical distance between the peak and its lowest contour line) and width of a

Figure 4: Eye gaze regions and mouth aspect ratio (MAR). The gaze angle is discretized into nine different gaze regions, including the center (gazing towards the camera lens) (a). MAR is calculated based on the height and width of the mouth (b).

peak. Heuristically, we found a threshold of 0.026 to provide the best results. We found that taking into account the width of the peaks is necessary to accurately detect peaks belonging to eye blinks because the prominence of the peaks differs among users and head pose. We extract the number of blinks and the basic statistics of the duration between blinks, the prominence, and the width of each blink. In addition, inspired by interbeat intervals (time interval between individual heartbeats) and the calculation of heartbeats thereof, we linearly interpolate the duration between two consecutive peaks surviving the threshold (i.e., eye blinks) to infer a continuous signal. We then calculate the number of eye blinks for every frame by taking the inverse of this interpolated signal. Subsequently, we again calculate the basic statistics over the number of eye blinks.

Eye gaze. The intention behind features related to eye gaze is that individuals might look away when thinking while solving math tasks or when looking at emotionally disturbing pictures. Thus, we compute the basic statistics on the angle in the x-direction (looking left-right) and y-direction (looking up-down) of the eye gaze averaged for both eyes and measured in radians in world coordinates. In addition, we discretize the eye gaze angle by defining nine different gaze regions (see Figure 4a). The center corresponds to a line of gaze directed towards the camera lens. For each of the nine regions, we count the number of occurrences and normalize it over $s * \text{fps}$, where s is the window size and fps is the frame rate per second (so that it is independent of the used camera, i.e., the frame rate).

Mouth aspect ratio. Previously, the mouth aspect ratio (MAR) was used to detect driver drowsiness [52]. It is defined by the ratio between the height and the width of the mouth, which is increased when opening the mouth (see Figure 4b):

$$\text{MAR} = \frac{\|p_2 - p_8\| + \|p_3 - p_7\| + \|p_4 - p_6\|}{3 * \|p_5 - p_1\|}. \quad (5)$$

Each point $p_i, \forall i \in \{1, \dots, 8\}$, is defined as the average of the inner and outer mouth landmarks. From the MAR, we calculate the basic statistics.

Head Movement. From the longest head moving sequence of an individual in the window, we extract the position of the first frame of the sequence in relation to the beginning of the window, the duration of the movement, and the total distance of the movement. The position of the first frame and the duration are normalized by $s * \text{fps}$. We also sum up the total

Figure 5: Fidgeting of a user. From the original image (a), the fidgeting image (b) is calculated by pixel-wise thresholding the difference of the current (a) to the past grayscale images.

distance moved over the entire window to capture individuals continually moving back and forth. In addition, we calculate the basic statistics of the velocity and acceleration of the head movements in the window. All these features are extracted for the x-axis, y-axis, and z-axis separately. Finally, we also extract the basic statistics of the distance of the head to the camera in the three-dimensional space.

Fidgeting. Navarathna et al. [42] introduced a fidgeting index for predicting movie ratings from audience behavior by calculating the total energy individuals are using for the movement. In contrast to features related to the head movement, fidgeting captures all the movement in the video (i.e., also body and face). First, we define the grayscale adaptive background b_{gray} , which is a weighted average of past frames. To calculate the energy E for a new frame f_{gray} (converted into grayscale), we subtract the adaptive background b_{gray} from f_{gray} , binarize the image by thresholding it, and then calculating the percentage of surviving pixels with respect to the camera resolution (see Figure 5b). We have chosen the threshold such that noise from the background is minimized, and the visibility of movements is maximized. Finally, the adaptive background is updated using

$$b_{\text{gray}} = (1 - a) * b_{\text{gray}} + a * f_{\text{gray}}, \quad (6)$$

where a is a weight term (we found $a = 0.2$ to provide the qualitatively best results). From the energy E of each frame in the window, we calculate basic statistics, sum up the energies over all frames and use the position of the frame with minimum and maximum energy normalized by $s * \text{fps}$.

4.3 Classification

We build the ground truth for our classifiers by splitting valence and arousal into two levels (high and low). We then use classifiers to predict these levels based on the features extracted from the camera recordings. In addition, we remove features having a correlation greater than a threshold, select features based on the ANOVA F-value between the class labels and the features, and standardize the features to have zero mean and unit variance. We use four different classifiers (i.e., Random Forest, Support Vector Machine, k-Nearest Neighbors and Gaussian Naive Bayes) because these classifiers have been most promising in initial tests and they have shown to provide good results for predicting affective states from video data in other works [25, 10, 6]. We use leave-one-user-out cross-validation to evaluate our models, which ensures that data of a participant is not used for training and testing at the same time. Finally, we optimize the hyperparameters (i.e., number of selected features, the threshold for

removing correlated features, and parameters of the model) using random search with nested cross-validation.

5. RESULTS

We conducted a qualitative and quantitative evaluation of our mirror setup and image processing pipeline with neural inpainting and investigated the applicability of our setup to predict affective states during math-solving tasks (active) and during exposure to emotional stimuli from images (passive). For training the neural inpainting model, we have used the celebA-HQ dataset [27] consisting of 30000 face aligned colored images from celebrities with a resolution of 1024×1024 pixels (we downsampled the images to 512×512 pixels). We split the dataset into a training set of 25000 images, a test set of 2500 images and a validation set of 2500 images. We set the parameters for the network in the same way as proposed by Liu et al. [34]. The results of the affective state prediction are based on a Random Forest classifier since this was the best performing model. Hyperparameters were optimized using random search with 50 iterations. Finally, for measuring the performance of our model, we used the area under curve (AUC) of the receiver operating characteristic curve and accuracy (chance level = 0.5).

5.1 Experiment

We reused a dataset that we collected in a controlled lab experiment [53]. The dataset consists of data from 88 participants (45 female) from age 18 to 29 (mean = 22.1, standard deviation SD = 2.0) of university students in the bachelor program. The participants used a Huawei MediaPad M2 10.0 tablet running Android 5.1 during the experiment. They were recorded by the front camera (resolution of 1280×720 pixels) using our proposed mirror construction setup and a GoPro HERO3 camera (frame rate per second FPS of 59.94 and a resolution of 1920×1080 pixels) (see the setup in Figure 1a). Due to the varying load of the tablet during the experiment, the fps was variable (mean = 20.02, SD = 1.92). We resampled the recordings from the tablet and the GoPro to an fps of 25 and 60, respectively. To synchronize the timestamps between the GoPro and the tablet, a beep signal was played on the tablet before the start of each session.

The study procedure consisted of three main steps conducted on the tablet to collect baseline data and trigger different affective states. First, each participant was watching a seven minutes nature video, which served as a baseline. Second, the participants were presented 40 pictures in random order from the International Affective Picture System (IAPS) [30] for around 20 minutes. The IAPS is a collection of 1182 pictures standardized in terms of valence and arousal and is widely used in psychological research for the study of emotions. Each image was shown for ten seconds and was followed by a ten seconds fixation cross. The 40 images have been selected from the IAPS dataset such that a wide range of the valence-arousal space was covered.

Finally, each participant solved multiple-choice math tasks for approximately 30 minutes. The math tasks were selected from a collection of math tasks provided by ACT [1] and divided into three different conditions varying in difficulty level, available completion time, and monetary reward (participants were rewarded and penalized depending on the

correctness of the solution and started with a credit of CHF 40). In the repetitive condition, easy and repetitive (i.e., similar) tasks were presented with more than enough available time to solve the tasks and a minor reward (+CHF 0.2) and penalty (−CHF 0.2). In the challenge condition, tasks with medium difficulty levels were shown with sufficient time to solve the tasks, and a large monetary reward (+CHF 2) but an only minor penalty (−CHF 0.2). The overchallenge condition consisted of tasks with a high difficulty level, insufficient time to solve the tasks and a small monetary reward (+CHF 0.2) but a large penalty (−CHF 2). The tasks were presented in six blocks. Each block contained tasks from a specific condition, and each condition was assigned randomly to two blocks.

After each image and math task, participants were asked to fill in the self-assessment manikin (SAM) [7] to judge their current valence and arousal level on a 9-point Likert scale. To build our affective prediction model, we split the valence and arousal ratings of the participants into two classes (low $\in \{1, \dots, 3\}$ and high $\in \{7, \dots, 9\}$). For IAPS, the number of data points amounted to 843 (1206) and 1218 (982) for low and high valence (arousal), respectively. On the other hand, for math tasks, the number of low and high valence (arousal) ratings amounted to 724 (1380) and 1422 (726), respectively.

5.2 Face Recognition

We provide qualitative and quantitative results of our setup using neural inpainting. In particular, we compare our results to recordings taken by the GoPro camera.

Qualitative evaluation. Figure 6 shows the facial landmarks detected by OpenFace for three participants from the front camera without inpainting, using neural inpainting, and from the GoPro. The positions of the detected landmarks without inpainting are inferior compared to neural inpainting. For participant 3, the landmarks at the upper face (eyebrows, eyes, and nose) are misaligned without inpainting. Often no facial landmarks could be detected (see Figure 6 participants 1a and 2a). With our neural inpainting approach, we achieved a qualitatively good recovered image independent of the position of the missing region (e.g., eyes and mouth). It is noteworthy that the inpainting and facial landmark detection also worked for participants wearing glasses. The detected landmarks after neural inpainting are similar to the landmarks detected from the GoPro recordings (see Figure 6c). Depending on the position of the head, the landmarks of the eyes and the mouth can become locally condensed in the GoPro recordings, and it might be hard to distinguish slight facial movements. On the other hand, from the front camera, the recordings are frontal, and the variations of facial parts (e.g., eye and mouth) are better visible.

Quantitative evaluation. Table 1 presents the average confidence in landmark detection of OpenFace over all frames for the IAPS and math-solving tasks and the full recordings (including also parts not belonging to the IAPS and math tasks). Reported confidence values by OpenFace are between 0 (not confident) and 1 (fully confident). Without inpainting, the confidence values are low, and standard deviations are high due to the imperfect recognition of landmarks. Without inpainting landmarks were often only detected correctly

Figure 6: Recordings of three participants. The facial landmarks were detected from the front camera recordings without inpainting (a) and with neural inpainting (b) and from the external GoPro camera (c). If no landmarks are visible, no landmarks were detected by OpenFace.

Table 1: Means of framewise confidence in landmark detection for different camera sources, tasks (math and IAPS) and the full recordings. Confidence values range from 0 (not confident) to 1 (fully confident). Standard deviations are given in brackets.

Source	IAPS	Math	Complete
Front (no inpainting)	0.79 (0.36)	0.48 (0.45)	0.68 (0.42)
Front (inpainting)	0.94 (0.14)	0.90 (0.22)	0.93 (0.18)
GoPro	0.97 (0.08))	0.93 (0.17)	0.95 (0.12)

when the missing regions were situated above the eyebrows (i.e., no landmarks have been affected). After applying neural inpainting, the confidence values increased by 19 % and 88 % during IAPS and math sequences, respectively. When considering the full video recordings, the increase amounts to 37 %. In addition, the standard deviation decreased substantially. This increase of the confidence leads to an increase in the number of samples (if a window used during feature extraction contained less than 80 % frames with a confidence value above 0.82 we discarded the corresponding data point). For IAPS, this lead to 348 and 383 additional samples for valence and arousal, respectively. For the math tasks, this amounted to 1233 and 1179 additional samples for valence and arousal, respectively. Finally, the confidence in landmark detection of the GoPro recordings is comparable to the front camera recordings with neural inpainting. In general, for recordings taken during exposure to a stimulus set of images

Table 2: Performance of Random Forest on the math and IAPS data from two levels (low and high) of valence and arousal based on the front camera recordings with neural inpainting and the GoPro recordings. The chance level for accuracy and AUC is 0.5.

Source	Data	AUC	Accuracy
Front camera	Math (valence)	0.73	68 %
	Math (arousal)	0.54	57 %
	IAPS (valence)	0.80	73 %
	IAPS (arousal)	0.70	66 %
GoPro	Math (valence)	0.76	72 %
	Math (arousal)	0.58	62 %
	IAPS (valence)	0.78	72 %
	IAPS (arousal)	0.73	67 %

the mean confidence is higher than during math tasks. This can be attributed to the fact that while solving math tasks, participants were moving more, which leads more often to suboptimal head positions for landmark detection. This finding is also reflected in the higher standard deviations of the confidence values for math tasks.

5.3 Classification Performance

Before predicting the affective states, the reconstructed front camera recordings and the GoPro recordings were preprocessed (see Section 4.1). Features were extracted using a ten seconds window encompassing the on-screen time of each pic-

Table 3: Number of occurrences of each feature type in the ten most predictive features. The numbers are provided for each of the four models (MV = math valence, MA = math arousal, IV = IAPS valence, IA = IAPS arousal).

Feature Type	MV	MA	IV	IA
Action units	0	2	2	3
Eye blinks	1	4	0	1
Eye gaze	1	2	2	0
Mouth aspect ratio	0	0	0	0
Head Movement	5	2	5	6
Fidgeting	3	0	1	0

ture and the last ten seconds of each math task because each picture was presented for ten seconds and the minimum task duration was ten seconds (see Section 4.2). Table 2 presents the performance of our model for predicting two levels (low and high) of valence and arousal. Based on the findings that the confidence in landmark detection increased up to 88% with neural inpainting, we used only the front camera recordings with neural inpainting. Using these recordings, our model achieved a performance of 0.73 AUC and 0.80 AUC for predicting valence on math tasks and IAPS, respectively. For predicting arousal, the performance drops and is only at random level for math tasks (0.54 AUC), while for IAPS it is above random (0.70 AUC). A similar pattern is visible for the GoPro recordings. While for predicting arousal based on the math tasks, the performance is close to random (0.58 AUC), all other predictions are above random. In summary, the predictions using the front camera are comparable to using the GoPro recordings with a maximum difference of 0.04 AUC. For predicting valence based on IAPS, the performance from the front camera recordings (0.80 AUC) exceeds the performance achieved by using the GoPro (0.78 AUC).

Feature importance. Table 3 presents the number of occurrences of each feature type in the ten most important features for each of the four models. We analyzed the feature importance using the Gini importance measure provided by the Random Forest classifier. Features related to head movement contributed the most for predicting valence based on math tasks (five features) and valence and arousal based on IAPS (five and six features). For predicting arousal based on math tasks, eye blinks provided four out of the ten most important features. There were no MAR features among the top ten features for any model. However, all feature types appeared in the top 30 ranked features of each model. For the model based on the math tasks, the maximum moved distance in the x-direction and the number of eye blinks were the highest scoring features for predicting valence and arousal, respectively. For the model based on IAPS, the mean acceleration in the x-direction and mean velocity in the x-direction were most important for predicting valence and arousal, respectively. Interestingly, head movement along the x-axis (left and right) was more informative than along the z-axis (forward and backward).

5.4 Runtime

We conducted a runtime analysis of the different parts of our inpainting pipeline and affective state prediction model. Our computing environment consisted of an Intel® Core™ CPU

i9-9900K @ 3.60GHz and an NVIDIA GeForce® RTX 2080 Ti. Processing one frame consisted of flattening the splitting boundary, face composition, image rotation and extracting the face area (mean = 17.07 ms, SD = 4.74 ms), detecting the position of the eyes using dlib (mean = 74.66 ms, SD = 6.43 ms), using the deep learning model to inpaint missing regions in the face (mean = 76.25 ms, SD = 13.81 ms) and inpainting the background of the image (mean = 47.01 ms, SD = 11.87 ms). Summing up these values leads to a processing time for one frame of 214.99 ms. Prediction of a new data point consisted of feature extraction (mean = 16.37 ms, SD = 2.18 ms) and using the Random Forest classifier for predicting valence and arousal (mean = 6.43 ms, SD = 10.52 ms), leading to a total prediction time of 22.8 ms.

6. DISCUSSION

Our findings show that it is possible to use our tablet-based front camera setup and processing pipeline to accurately capture users for extracting features such as facial landmarks and movement of the head and body. Our neural inpainting pipeline provides a qualitatively accurate restoration of missing regions caused by our mirror construction setup and increases the confidence in landmark detection by up to 88%. Compared to recordings from a GoPro camera, our setup provides better results in terms of face visibility (frontal view). Thus, it potentially facilitates the recognition of minor facial movements (e.g., mouth and eyes). In particular, for solving math tasks we found the recording conditions of the GoPro more challenging due to the viewing angle (participants were bending over the tablet). This resulted in lower confidence in landmark detection (0.93 for math tasks versus 0.97 for IAPS). Similarly, the front camera recordings with neural inpainting showed higher confidence in landmark detection during IAPS (0.94) compared to solving math tasks (0.90). During the exposure to a stimulus set of images from the IAPS dataset, participants were sitting straight, implicating that the splitting boundary was located at the forehead, which made inpainting easier. In contrast, during solving math tasks, the splitting boundary was often located in the middle (eye) or lower part of the face (mouth), creating a more challenging situation for our neural inpainting model.

We showed the applicability of our setup for predicting affective states during active (math-solving) and passive (exposure to pictures) tasks based on the recordings from the front camera. Our model achieved better performance on IAPS (up to 0.80 AUC) than on the math tasks (up to 0.73 AUC). Due to the active involvement of the participants while solving math tasks, participants were moving more, which made accurate tracking of facial landmarks, AUs, and eye gaze more demanding. In addition, our model performed better for predicting valence (0.73 AUC and 0.80 AUC) than arousal (0.54 AUC and 0.70 AUC). One-third of the participants rated arousal constantly as low or high without showing much variation. This finding can affect the generalization of our model to other participants for predicting arousal. In addition, although affective states are universal, they also have components that are individual to a person [18]. This makes it harder to predict an affective state of a person without having training data available of that person. Comparing the performance of our affective prediction pipeline to other research is difficult because most existing work [10, 57] predicted basic emotions and used other settings.

Our analysis of the feature importance showed that head movement is a predictive feature in contrast to MAR. Some AUs capture movements of the mouth. Thus, we analyzed the correlation between MAR and AUs specific to the mouth region. The correlations between the MAR feature and the AUs specifying lip corner puller (-0.15 , $p\text{-value} = 0.15$), opening the mouth (0.25 , $p\text{-value} = 0.13$) and jaw drop (0.045 , $p\text{-value} = 0.26$) have all been low and not significant.

In comparison to recordings from the GoPro, our model based on front camera recordings performed equally well and even better for predicting valence on IAPS (0.80 AUC versus 0.78 AUC). This renders our setup a viable alternative to more expensive equipment such as a GoPro. Our setup comes at low costs (CHF 5), is unobtrusive, can easily be mounted, is flexible in the application (e.g., in classrooms or at home), and eliminates the need for synchronizing different devices. In contrast to external cameras, the camera (i.e., the lens) in our setup is small and unobtrusive. Some participants reported after the experiment that they got slightly distracted by the GoPro but not by our mirror setup. Similarly, in the video recordings, we recognized that participants were sometimes glancing at the GoPro. Finally, with a processing time of 214.99 ms per frame, our pipeline can handle four frames per second. Our affective prediction pipeline is capable of making 43 new predictions every second.

Limitations. We acknowledge potential limitations to our approach presented in this paper. Our setup is constrained by the lighting conditions, head pose, and occlusions from hand movement. We believe that other camera setups suffer from the same constraints. Further, our mirror construction is a prototype and not yet ready for production. Although during the experiment the construction proved to be stable, it can be improved in terms of stability and flexibility. Neural inpainting provided qualitatively satisfactory results for most facial parts. However, if the splitting boundary is covering the eyes (i.e., both eyes are occluded), it is hard for the inpainting model to reconstruct the eyes at a qualitatively high level. Consequently, the landmark detection cannot recover eye gaze and eye blinks, but still detects other facial features. In addition, although the CelebA-HQ dataset consists of facial images from celebrities with diverse ethnicity, age and facial characteristics (e.g., glasses and facial hair), our inpainting method might be less appropriate for students who are underrepresented in the CelebA-HQ dataset. We further acknowledge that our experiment is restricted to math tasks and exposure to emotional stimuli from pictures in a lab environment with bachelor students. We are optimistic that our approach generalizes to a broader population and to other tasks given that we used active (math-solving) and passive (exposure to pictures) tasks and assuming a proper baseline normalization of the features. Finally, we have predicted valence and arousal on two levels omitting data points in the medium range (4 to 6). Our main contribution is the novel mirror construction and the processing pipeline. We have mainly built our affective prediction model for demonstrating the applicability of our setup. Nevertheless, we believe that our features and pipeline can be interesting for other researchers predicting affective states based on video data.

Future work. Future research comprises refining and extending our hardware setup and inpainting pipeline, as well as evaluating our affective prediction model in other domains. In particular, realtime performance would be desirable for on-the-spot assessment of a student's affective state. The CelebA-HQ dataset, which we used to train our inpainting model, contains only images with a frontal view of faces. In our recordings, individuals are captured at different angles. Thus, rotation of the recordings or using a dataset providing faces at different angles can improve the neural inpainting model. In addition, a deep learning model could be trained on our features for affective prediction, and the feature set could be extended by gesture-based features. Such features have shown to be promising for predicting affective states [9].

7. CONCLUSION

In this paper, we presented a hardware setup consisting of a cheap and unobtrusive mirror construction to improve the visibility of the face in tablet-based front camera recordings. Recordings were processed using an inpainting pipeline consisting of a neural network for reconstructing missing data in the recordings. We showed that the mirror construction improved the visibility of the face in situations where external cameras (e.g., GoPro) struggle. With a qualitative and quantitative evaluation, we demonstrated that we could achieve results comparable to a GoPro camera. In particular, neural inpainting improved confidence in facial landmark detection by up to 88% . We showed the applicability of our setup and processing pipeline on affective state prediction based on front camera recordings. Our model consisted of features capturing information from movement, eyes, and face. We evaluated our affective prediction model on data from a lab experiment with 88 participants using leave-one-user-out cross-validation. Participants were solving math tasks (active) and were exposed to emotional stimuli from pictures (passive). Our model accurately predicted two levels (low and high) of valence (up to 0.80 AUC) and arousal (up to 0.73 AUC) using data from the front camera. These results were comparable to results obtained using recordings from a GoPro camera (up to 0.78 AUC for valence and up to 0.73 AUC for arousal). The novelty of our contribution consists of the hardware setup and processing pipeline. In addition, we proposed features for affective state prediction, which can be useful for other researchers. Our setup is cheap (CHF 5), easy to mount, and can be used in classrooms or at home. Besides affective state prediction, it can be used to monitor students or analyzing attention. Most existing approaches use external cameras such as GoPros or webcams, which are more expensive, more difficult to handle, and are exposed to time synchronization problems. In our setup, the camera data is recorded on the same device as the task is conducted, and thus we circumvent such time synchronization issues in an elegant way. The findings of this work are important because they support the emerging trend of using tablet computers in the classroom and for learning at home by simplifying student recording and assessment.

ABSTRACT

Item Response Theory (IRT) is a ubiquitous model for understanding humans based on their responses to questions, used in fields as diverse as education, medicine and psychology. Large modern datasets offer opportunities to capture more nuances in human behavior, potentially improving test scoring and better informing public policy. Yet larger datasets pose a difficult speed / accuracy challenge to contemporary algorithms for fitting IRT models. We introduce a variational Bayesian inference algorithm for IRT, and show that it is fast and scaleable without sacrificing accuracy. Using this inference approach we then extend classic IRT with expressive Bayesian models of responses. Applying this method to five large-scale item response datasets from cognitive science and education yields higher log likelihoods and improvements in imputing missing data. The algorithm implementation is open-source, and easily usable.

1. INTRODUCTION

The task of estimating human ability from stochastic responses to a series of questions has been studied since the 1950s in thousands of papers spanning several fields. The standard statistical model for this problem, Item Response Theory (IRT), is used every day around the world, in many critical contexts including college admissions tests, school-system assessment, survey analysis, popular questionnaires, and medical diagnosis.

As datasets become larger, new challenges and opportunities for improving IRT models present themselves. On the one hand, massive datasets offer the opportunity to better understand human behavior, fitting more expressive models. On the other hand, the algorithms that work for fitting small datasets often become intractable for larger data sizes. Indeed, despite a large body of literature, contemporary IRT methods fall short – it remains surprisingly difficult to estimate human ability from stochastic responses. One crucial bottleneck is that the most accurate, state-of-the-art Bayesian inference algorithms are prohibitively slow, while

faster algorithms (such as the popular maximum marginal likelihood estimators) are less accurate and poorly capture uncertainty. This leaves practitioners with a choice: either have nuanced Bayesian models with appropriate inference or have timely computation.

In the field of artificial intelligence, a revolution in deep generative models via *variational inference* [25, 37] has demonstrated an impressive ability to perform fast inference for complex Bayesian models. In this paper, we present a novel application of variational inference to IRT, validate the resulting algorithms with synthetic datasets, and apply them to real world datasets. We then show that this inference approach allows us to extend classic IRT response models with deep neural network components. We find that these more flexible models better fit the large real world datasets. Specifically, our contributions are as follows:

1. **Variational inference for IRT:** We derive a new optimization objective — the Variational Item response theory Lower Bound, or VIBO — to perform inference in IRT models. By learning a mapping from responses to posterior distributions over ability and items, VIBO is “amortized” to solve inference queries efficiently.
2. **Faster inference:** We find VIBO to be much faster than previous Bayesian techniques and usable on much larger datasets without loss in accuracy.
3. **More expressive:** Our inference approach is naturally compatible with deep generative models and, as such, we enable the novel extension of Bayesian IRT models to use neural-network-based representations for inputs, predictions, and student ability. We develop the first deep generative IRT models.
4. **Simple code:** Using our VIBO python package¹ is only a few lines of code that is easy to extend.
5. **Real world application:** We demonstrate the impact of faster inference and expressive models by applying our algorithms to datasets including: PISA, DuoLingo and Gradescope. We achieve up to 200 times speedup and show improved accuracy at imputing hidden responses. At scale, these improvements in efficiency save hundreds of hours of computation.

¹<http://github.com/mhw32/variational-item-response-theory-public>

As a roadmap, in Sec. 2 we describe the item response theory challenge. In Sec. 3 we present a main algorithm. Finally, in Sec. 4 and 5 we show its impact on speed and accuracy.

2. BACKGROUND

We briefly review several variations of item response theory and the fundamental principles of approximate Bayesian inference, focusing on modern variational inference.

2.1 Item Response Theory Review

Imagine answering a series of multiple choice questions. For example, consider a personality survey, a homework assignment, or a school entrance examination. Selecting a response to each question is an interaction between your “ability” (knowledge or features) and the characteristics of the question, such as its difficulty. The goal in examination analysis is to gauge this unknown ability of each student and the unknown item characteristics based only on responses. Early procedures [11] defaulted to very simple methods, such as counting the number of correct responses, which ignore differences in question quality. In reality, we understand that not all questions are created equal: some may be hard to understand while others may test more difficult concepts. To capture these nuances, Item Response Theory (IRT) was developed as a mathematical framework to reason jointly about people’s ability and the items themselves.

The IRT model plays an impactful role in many large institutions. It is the preferred method for estimating ability in several state assessments in the United States, for international assessments gauging educational competency across countries [18], and for the National Assessment of Educational Programs (NAEP), a large-scale measurement of literacy and reading comprehension in the US [35]. Beyond education, IRT is a method widely used in cognitive science and psychology, for instance with regards to studies of language acquisition and development [19, 28, 14, 7].

Figure 1: Graphical models for the (a) 1PL, (b) 2PL, and (c) 3PL Item Response Theories. Observed variables are shaded. Arrows represent dependency between random variables and each rectangle represents a plate (i.e. repeated observations).

IRT has many forms; we review the most standard (Fig. 1). The simplest class of IRT summarizes the ability of a person with a single parameter. This class contains three versions: 1PL, 2PL, and 3PL IRT, each of which differ by the number of free variables used to characterize an item. The 1PL IRT model, also called the Rasch model [34], is given in Eq. 1,

$$p(r_{i,j} = 1 | a_i, d_j) = \frac{1}{1 + e^{-(a_i - d_j)}} \quad (1)$$

where $r_{i,j}$ is the response by the i -th person to the j -th item. There are N people and M items in total. Each

item in the 1PL model is characterized by a single number representing difficulty, d_j . As the 1PL model is equivalent to a logistic function, a higher difficulty requires a higher ability in order to respond correctly. Next, the 2PL IRT model² adds a *discrimination* parameter, k_j for each item that controls the slope (or scale) of the logistic curve. We can expect items with higher discrimination to more quickly separate people of low and high ability. The 3PL IRT model further adds a *pseudo-guessing* parameter, g_j for each item that sets the asymptotic minimum of the logistic curve. We can interpret pseudo-guessing as the probability of success if the respondent were to make a reasonable guess on an item. The 2PL and 3PL IRT models are:

$$p(r_{i,j} | a_i, \mathbf{d}_j) = \frac{1}{1 + e^{-k_j a_i - d_j}} \text{ or } g_j + \frac{1 - g_j}{1 + e^{-k_j a_i - d_j}} \quad (2)$$

where $\mathbf{d}_j = \{k_j, d_j\}$ for 2PL and $\mathbf{d}_j = \{g_j, k_j, d_j\}$ for 3PL. See Fig. 1 for graphical models of each of these IRT models.

A single ability dimension is sometimes insufficient to capture the relevant variation in human responses. For instance, if we are measuring a person’s understanding on elementary arithmetic, then a single dimension may suffice in capturing the majority of the variance. However, if we are instead measuring a person’s general mathematics ability, a single real number no longer seems sufficient. Even if we bound the domain to middle school mathematics, there are several factors that contribute to “mathematical understanding” (e.g. proficiency in algebra versus geometry). Summarizing a person with a single number in this setting would result in a fairly loose approximation. For cases where multiple facets of ability contribute to performance, we consider *multidimensional* item response theory [1, 36, 29]. We focus on 2PL multidimensional IRT (MIRT):

$$p(r_{i,j} = 1 | \mathbf{a}_i, \mathbf{k}_j, d_j) = \frac{1}{1 + e^{-\mathbf{a}_i^T \mathbf{k}_j - d_j}} \quad (3)$$

where we use bolded notation $\mathbf{a}_i = (a_i^{(1)}, a_i^{(2)}, \dots, a_i^{(K)})$ to represent a K dimensional vector. Notice that the item discrimination becomes a vector of equal size to ability.

In practice, given a (possibly incomplete) $N \times M$ matrix of observed responses, we want to *infer* the ability of all N people and the characteristics of all M items. Next, we provide a brief overview of inference in IRT.

2.2 Inference in Item Response Theory

Inference is the task of estimating unknown variables, such as ability, given observations, such as student responses. We compare and contrast three popular methods used to perform inference for IRT in research and industry. Inference algorithms are critical for item response theory as slow or inaccurate algorithms prevent the use of appropriate models.

Maximum Likelihood Estimation A straightforward approach is to pick the most likely ability and item features

²We default to 2PL as the pseudo-guessing parameter introduces several invariances in the model. This requires far more data to infer ability accurately, as measured by our own synthetic experiments. For practitioners, we warn against using 3PL for small to medium datasets.

given the observed responses. To do so we optimize:

$$\mathcal{L}_{\text{MLE}} = \max_{\{\mathbf{a}_i\}_{i=1}^N, \{\mathbf{d}_j\}_{j=1}^M} \sum_{i=1}^N \sum_{j=1}^M \log p(r_{ij} | \mathbf{a}_i, \mathbf{d}_j) \quad (4)$$

with stochastic gradient descent (SGD). The symbol \mathbf{d}_j represents all item features e.g. $\mathbf{d}_j = \{d_j, \mathbf{k}_j\}$ for 2PL. Eq. 4 is often called the Joint Maximum Likelihood Estimator [3, 12], abbreviated MLE. MLE poses inference as a supervised regression problem in which we choose the most likely unknown variables to match known dependent variables. While MLE is simple to understand and implement, it lacks any measure of uncertainty; this can have important consequences especially when responses are missing.

Expectation Maximization Several papers have pointed out that when using MLE, the number of unknown parameters increases with the number of people [5, 17]. In particular, [17] shows that in practical settings with a finite number of items, standard convergence theorems do not hold for MLE as the number of people grows. To remedy this, the authors instead treat ability as a nuisance parameter and marginalized it out [5, 6]. Brock et. al. introduces an Expectation-Maximization (EM) [10] algorithm to iterate between (1) updating beliefs about item characteristics and (2) using the updated beliefs to define a marginal distribution (without ability) $p(r_{ij} | \mathbf{d}_j)$ by numerical integration of \mathbf{a}_i . Appropriately, this algorithm is referred to as Maximum Marginal Likelihood Estimation, which we abbreviate as EM. Eq. 6 shows the E and M steps for EM.

$$\text{E step: } p(r_{ij} | \mathbf{d}_j^{(t)}) = \int_{\mathbf{a}_i} p(r_{ij} | \mathbf{a}_i, \mathbf{d}_j^{(t)}) p(\mathbf{a}_i) d\mathbf{a}_i \quad (5)$$

$$\text{M step: } \mathbf{d}_j^{(t+1)} = \arg \max_{\mathbf{d}_j} \sum_{i=1}^N \log p(r_{ij} | \mathbf{d}_j^{(t)}) \quad (6)$$

where (t) represents the iteration count. We often choose $p(\mathbf{a}_i)$ to be a simple prior distribution like standard Normal. In general, the integral in the E-step is intractable: EM uses a Gaussian-Hermite quadrature to discretely approximate $p(r_{ij} | \mathbf{d}_j^{(t)})$. See [20] for a closed form expression for $\mathbf{d}_j^{(t+1)}$ in the M step. This method finds the maximum a posteriori (MAP) estimate for item characteristics. EM does not infer ability as it is “ignored” in the model: the common workaround is to use EM to infer item characteristics, then fit ability using a second auxiliary model. In practice, EM has grown to be ubiquitous in industry as it is incredibly fast for small to medium sized datasets. However, we expect that EM may scale poorly to large datasets and higher dimensions as numerical integration requires far more points to properly measure a high dimensional volume.

Hamiltonian Monte Carlo The two inference methods above give only point estimates for ability and item characteristics. In contrast Bayesian approaches seek to capture the full posterior over ability and item characteristics given observed responses, $p(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})$ where $\mathbf{r}_{i,1:M} = (r_{i,1}, \dots, r_{i,M})$. Doing so provides estimates of uncertainty and characterizes features of the joint distribution that cannot be represented by point estimates, such as multimodality and parameter correlation. In practice, this can be very useful for a more robust understanding of student ability.

The common technique for Bayesian estimation in IRT uses Markov Chain Monte Carlo (MCMC) [21, 15] to draw samples from the posterior by constructing a Markov chain carefully designed such that $p(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})$ is the equilibrium distribution. By running the chain longer, we can closely match the distribution of drawn samples to the true posterior. Hamiltonian Monte Carlo (HMC) [33, 32, 23] is an efficient version of MCMC for continuous state spaces. We recommend [23] for a good review of HMC.

The strength of this approach is that the samples generated capture the true posterior (if the algorithm is run long enough). But the computational costs for MCMC can be very high, and the cost scales at least linearly with the number of latent parameters — which for IRT is proportional to data size. With new datasets of millions of observations, such limitations can be debilitating. Fortunately, there exist a second class of approximate Bayesian techniques that have gained significant traction in the machine learning community. We provide a careful review of *variational inference*.

2.3 Variational Methods Review

Variational inference (VI) first appeared from the statistical physics community and was later generalized for many probabilistic models by Jordan et. al. [24]. In recent years, VI has been popularized in machine learning where it is used to do inference in large graphical models describing images and natural language. The main intuition of variational inference is to treat inference as an optimization problem: starting with a family of distributions, the goal is to pick the one that best approximates the true posterior, by minimizing an estimate of the mismatch between true and approximate distributions. We will first describe VI in the general context of a latent variable model, and then apply VI to IRT.

Let $\mathbf{x} \in \mathcal{X}$ and $\mathbf{z} \in \mathcal{Z}$ represent observed and latent variables, respectively. (In the context of IRT, \mathbf{x} represents the responses from a single student and \mathbf{z} represents ability and item characteristics.) In VI [24, 42, 4], we introduce a family of tractable distributions over \mathbf{z} such that we can easily sample from and score. We wish to find the member $q_{\psi^*(\mathbf{x})} \in \mathcal{Q}$ that minimizes the Kullback-Leibler (KL) divergence between itself and the true posterior:

$$q_{\psi^*(\mathbf{x})}(\mathbf{z}) = \arg \min_{q_{\psi(\mathbf{x})}} D_{\text{KL}}(q_{\psi(\mathbf{x})}(\mathbf{z}) || p(\mathbf{z} | \mathbf{x})) \quad (7)$$

where $\psi(\mathbf{x})$ are parameters that define each distribution. For example, $\psi(\mathbf{x})$ would be the mean and scale for a Gaussian distribution. Since the “best” approximate posterior $q_{\psi^*(\mathbf{x})}$ depends on the observed variables, its parameters have \mathbf{x} as a dependent variable. To be clear, there is one approximate posterior for every possible value of the observed variables.

Frequently, we need to do inference for many different values of \mathbf{x} . For example, student A and student B may have picked different answers to the same question. Since their responses differ, we would need to do inference twice. Let $p_{\mathcal{D}}(\mathbf{x})$ be an empirical distribution over the observed variables, which is equivalent to the marginal $p(\mathbf{x})$ if the generative model is correctly specified. Then, the average quality of the variational approximations is measured by

$$\mathbb{E}_{p_{\mathcal{D}}(\mathbf{x})} \left[\max_{\psi(\mathbf{x})} \mathbb{E}_{q_{\psi(\mathbf{x})}(\mathbf{z})} \left[\log \frac{p(\mathbf{x}, \mathbf{z})}{q_{\psi(\mathbf{x})}(\mathbf{z})} \right] \right] \quad (8)$$

In practice, $p_{\mathcal{D}}(\mathbf{x})$ is unknown but we assume access to a dataset \mathcal{D} of examples i.i.d. sampled from $p_{\mathcal{D}}(\mathbf{x})$; this is sufficient to evaluate Eq. 8.

Amortization As in Eq. 8, we must learn an approximate posterior for each $\mathbf{x} \in \mathcal{D}$. For a large dataset \mathcal{D} , this can quickly grow to be unwieldy. One such solution to this scalability problem is *amortization* [16], which reframes the per-observation optimization problem as a supervised regression task. Consider learning a single deterministic mapping $f_{\phi} : \mathcal{X} \rightarrow \mathcal{Q}$ to predict $\psi^*(\mathbf{x})$ or equivalently $q_{\psi^*(\mathbf{x})} \in \mathcal{Q}$ as a function of the observation \mathbf{x} . Often, we choose f_{ϕ} to be a conditional distribution, denoted by $q_{\phi}(\mathbf{z}|\mathbf{x}) = f_{\phi}(\mathbf{x})(\mathbf{z})$.

The benefit of amortization is a large reduction in computational cost: the number of parameters is vastly smaller than learning a per-observation posterior. Additionally, if we manage to learn a good regressor, then the amortized approximate posterior $q_{\phi}(\mathbf{z}|\mathbf{x})$ could generalize to new observations $\mathbf{x} \notin \mathcal{D}$ unseen in training. This strength has made amortized VI popular with modern latent variable models, such as the Variational Autoencoder [25].

Instead of Eq. 8, we now optimize:

$$\max_{\phi} \mathbb{E}_{p_{\mathcal{D}}(\mathbf{x})} \left[\mathbb{E}_{q_{\phi}(\mathbf{z}|\mathbf{x})} \left[\log \frac{p(\mathbf{x}, \mathbf{z})}{q_{\phi}(\mathbf{z}|\mathbf{x})} \right] \right] \quad (9)$$

The drawback of this approach is that it introduces an *amortization gap*: since we are technically using a less flexible family of approximate distributions, the quality of approximate posteriors can be inferior.

Model Learning So far we have assumed a fixed generative model $p(\mathbf{x}, \mathbf{z})$. However, often we can only specify a family of possible models $p_{\theta}(\mathbf{x}|\mathbf{z})$ parameterized by θ . The symmetric challenge (to approximate inference) is to choose θ whose model best explains the evidence. Naturally, we do so by maximizing the log marginal likelihood of the data

$$\log p_{\theta}(\mathbf{x}) = \log \int_{\mathbf{z}} p_{\theta}(\mathbf{x}, \mathbf{z}) d\mathbf{z} \quad (10)$$

Using Eq. 9, we derive the Evidence Lower Bound (ELBO) [25, 37] with $q_{\phi}(\mathbf{z}|\mathbf{x})$ as our inference model

$$\log p_{\theta}(\mathbf{x}) \geq \mathbb{E}_{q_{\phi}(\mathbf{z}|\mathbf{x})} \left[\log \frac{p_{\theta}(\mathbf{x}, \mathbf{z})}{q_{\phi}(\mathbf{z}|\mathbf{x})} \right] \triangleq \text{ELBO} \quad (11)$$

We can jointly optimize ϕ and θ to maximize the ELBO. We have the option to parameterize $p_{\theta}(\mathbf{x}|\mathbf{z})$ and $q_{\phi}(\mathbf{z}|\mathbf{x})$ with deep neural networks, as is common with the VAE [25], yielding an extremely flexible space of distributions.

Stochastic Gradient Estimation The gradients of the ELBO (Eq. 11) with respect to ϕ and θ are:

$$\nabla_{\theta} \text{ELBO} = \mathbb{E}_{q_{\phi}(\mathbf{z}|\mathbf{x})} [\nabla_{\theta} \log p_{\theta}(\mathbf{x}, \mathbf{z})] \quad (12)$$

$$\nabla_{\phi} \text{ELBO} = \nabla_{\phi} \mathbb{E}_{q_{\phi}(\mathbf{z}|\mathbf{x})} [\log p_{\theta}(\mathbf{x}, \mathbf{z})] \quad (13)$$

Eq. 12 can be estimated using Monte Carlo samples. However, as it stands, Eq. 13 is difficult to estimate as we cannot distribute the gradient inside the inner expectation. For certain families \mathcal{Q} , we can use a reparameterization trick.

Reparameterization Estimators Reparameterization is the technique of removing sampling from the gradient

computation graph [25, 37]. In particular, if we can reduce sampling $\mathbf{z} \sim q_{\phi}(\mathbf{z}|\mathbf{x})$ to sampling from a parameter-free distribution $\epsilon \sim p(\epsilon)$ plus a deterministic function application, $\mathbf{z} = g_{\phi}(\epsilon)$, then we may rewrite Eq. 13 as:

$$\nabla_{\phi} \text{ELBO} = \mathbb{E}_{p(\epsilon)} [\nabla_{\mathbf{z}} \log \frac{p_{\theta}(\mathbf{x}, g_{\phi}(\epsilon))}{q_{\phi}(g_{\phi}(\epsilon)|\mathbf{x})} \nabla_{\phi} g_{\phi}(\epsilon)] \quad (14)$$

which now can be estimated efficiently by Monte Carlo (the gradient is inside the expectation). A benefit of reparameterization over alternative estimators (e.g. score estimator [30] or REINFORCE [44]) is lower variance while remaining unbiased. A common example is if $q_{\phi}(\mathbf{z}|\mathbf{x})$ is Gaussian $\mathcal{N}(\mu, \sigma^2)$ and we choose $p(\epsilon)$ to be $\mathcal{N}(0, 1)$, then $g(\epsilon) = \epsilon * \sigma + \mu$.

3. THE VIBO ALGORITHM

Having rehearsed the major principles of VI, we will adapt them to IRT. In our review, we presented the ELBO that serves as the primary loss function to train an inference model. Given the nuances of IRT, we can derive a new loss function specialized for ability and item characteristics. We call the resulting algorithm VIBO since it is a **V**ariational approach for **I**tem response theory based on a novel lower **B**ound. While the remainder of the section presents the technical details, we ask the reader to keep the high-level purpose in mind: VIBO is an objective function that if we maximize, we have a method to predict student ability from his or her responses. As an optimization problem, VIBO is much cheaper computationally than MCMC.

To show that doing so is justifiable, we prove that VIBO well-defined. That is, we must show that VIBO lower bounds the marginal likelihood over a student's responses.

THEOREM 3.1. *Let \mathbf{a}_i be the ability for person $i \in [1, N]$ and \mathbf{d}_j be the characteristics for item $j \in [1, M]$. We use the shorthand notation $\mathbf{d}_{1:M} = (\mathbf{d}_1, \dots, \mathbf{d}_M)$. Let $r_{i,j}$ be the binary response for item j by person i . We write $\mathbf{r}_{i,1:M} = (r_{i,1}, \dots, r_{i,M})$. If we define the VIBO objective as:*

$$\text{VIBO} \triangleq \mathcal{L}_{\text{recon}} + \mathbb{E}_{q_{\phi}(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [D_{\text{ability}}] + D_{\text{item}}$$

where

$$\mathcal{L}_{\text{recon}} = \mathbb{E}_{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [\log p_{\theta}(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})]$$

$$D_{\text{ability}} = D_{\text{KL}}(q_{\phi}(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M}) || p(\mathbf{a}_i))$$

$$D_{\text{item}} = D_{\text{KL}}(q_{\phi}(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M}) || p(\mathbf{d}_{1:M}))$$

and assume the joint posterior factors as $q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M}) = q_{\phi}(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M}) q_{\phi}(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})$, then $\log p(\mathbf{r}_{i,1:M}) \geq \text{VIBO}$. In other words, VIBO is a lower bound on the log marginal probability of person i 's responses.

PROOF. Expand marginal and apply Jensen's inequality:

$$\begin{aligned} \log p_{\theta}(\mathbf{r}_{i,1:M}) &\geq \mathbb{E}_{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \left[\log \frac{p_{\theta}(\mathbf{r}_{i,1:M}, \mathbf{a}_i, \mathbf{d}_{1:M})}{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \right] \\ &= \mathbb{E}_{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [\log p_{\theta}(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})] \\ &\quad + \mathbb{E}_{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \left[\log \frac{p(\mathbf{a}_i)}{q_{\phi}(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M})} \right] \\ &\quad + \mathbb{E}_{q_{\phi}(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \left[\log \frac{p(\mathbf{d}_{1:M})}{q_{\phi}(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \right] \\ &= \mathcal{L}_{\text{recon}} + \mathcal{L}_A + \mathcal{L}_B \end{aligned}$$

Rearranging the latter two terms, we find that:

$$\begin{aligned}\mathcal{L}_A &= \mathbb{E}_{q_\phi(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [D_{\text{KL}}(q_\phi(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M})||p(\mathbf{a}_i))] \\ \mathcal{L}_B &= \mathbb{E}_{q_\phi(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \left[\log \frac{p(\mathbf{d}_{1:M})}{q_\phi(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \right] \\ &= D_{\text{KL}}(q_\phi(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})||p(\mathbf{d}_{1:M}))\end{aligned}$$

Since $\text{VIBO} = \mathcal{L}_{\text{recon}} + \mathcal{L}_A + \mathcal{L}_B$, and KL terms are non-negative, we have shown that VIBO bounds $\log p_\theta(\mathbf{r}_{i,1:M})$. \square

Thm. 3.1 leaves several choices up to us, and we opt for the simplest ones. For instance, the prior distributions are chosen to be independent standard Normal distributions: $p(\mathbf{a}_i) = \prod_{k=1}^K p(a_{i,k})$ and $p(\mathbf{d}_{1:M}) = \prod_{j=1}^M p(\mathbf{d}_j)$ where $p(a_{i,k})$ and $p(\mathbf{d}_j)$ are $\mathcal{N}(0, 1)$. Further, we found it sufficient to assume $q_\phi(\mathbf{d}_{1:M}|\mathbf{r}_{i,1:M}) = q_\phi(\mathbf{d}_{1:M}) = \prod_{j=1}^M q_\phi(\mathbf{d}_j)$ although nothing prevents the general case. Initially, we assume the generative model, $p_\theta(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})$, to be an IRT model (thus θ is empty); later we explore generalizations.

Algorithm 1: VIBO Forward Pass

Assume we are given observed responses for person i , $\mathbf{r}_{i,1:M}$;
 Compute $\mu_{\mathbf{a}}, \sigma_{\mathbf{a}}^2 = q_\phi(\mathbf{d}_{1:M})$;
 Sample $\mathbf{d}_{1:M} \sim \mathcal{N}(\mu_{\mathbf{a}}, \sigma_{\mathbf{a}}^2)$;
 Compute $\mu_{\mathbf{a}}, \sigma_{\mathbf{a}}^2 = q_\phi(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M})$;
 Sample $\mathbf{a}_i \sim \mathcal{N}(\mu_{\mathbf{a}}, \sigma_{\mathbf{a}}^2)$;
 Compute $\mathcal{L}_{\text{recon}} = \log p_\theta(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})$;
 Compute $D_{\text{ability}} = D_{\text{KL}}(\mathcal{N}(\mu_{\mathbf{a}}, \sigma_{\mathbf{a}}^2)||\mathcal{N}(0, 1))$;
 Compute $D_{\text{item}} = D_{\text{KL}}(\mathcal{N}(\mu_{\mathbf{d}}, \sigma_{\mathbf{d}}^2)||\mathcal{N}(0, 1))$;
 Compute $\text{VIBO} = \mathcal{L}_{\text{recon}} + D_{\text{ability}} + D_{\text{item}}$

The posterior $q_\phi(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M})$ needs to be robust to missing data as often not every person answers every question. To achieve this, we explore the following family:

$$q_\phi(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M}) = \prod_{j=1}^M q_\phi(\mathbf{a}_i|\mathbf{d}_j, \mathbf{r}_{i,j}) \quad (15)$$

If we assume each component $q_\phi(\mathbf{a}_i|\mathbf{d}_j, \mathbf{r}_{i,j})$ is Gaussian, then $q_\phi(\mathbf{a}_i|\mathbf{d}_{1:M}, \mathbf{r}_{i,1:M})$ is Gaussian as well, being a Product-Of-Experts [22, 45]. If item j is missing, we replace its term in the product with the prior, $p(\mathbf{a}_i)$ representing no added information. We found this design to outperform averaging over non-missing entries: $\frac{1}{M} \sum_{j=1}^M q_\phi(\mathbf{a}_i|\mathbf{d}_j, \mathbf{r}_{i,j})$.

As VIBO is a close cousin of the ELBO, we can estimate its gradients with respect to θ and ϕ similarly:

$$\begin{aligned}\nabla_\theta \text{VIBO} &= \nabla_\theta \mathcal{L}_{\text{recon}} \\ &= \mathbb{E}_{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [\nabla_\theta \log p_\theta(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})] \\ \nabla_\phi \text{VIBO} &= \nabla_\phi \mathbb{E}_{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} [D_{\text{ability}}] + \nabla_\phi D_{\text{item}} \\ &= \nabla_\phi \mathbb{E}_{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \left[\frac{p(\mathbf{a}_i)p(\mathbf{d}_{1:M})}{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M}|\mathbf{r}_{i,1:M})} \right]\end{aligned}$$

As in Eq. 14, we may wish to move the gradient inside the KL divergences by reparameterization to reduce variance. To allow easy reparameterization, we define all variational distributions $q_\phi(\cdot|\cdot)$ as Normal distributions with diagonal covariance. In practice, we find that estimating $\nabla_\theta \text{VIBO}$ and $\nabla_\phi \text{VIBO}$ with a single sample is sufficient. With this setup,

VIBO can be optimized using stochastic gradient descent to learn an amortized inference model that maximizes the marginal probability of observed data. We summarize the required computation to calculate VIBO in Alg. 1.

4. DATASETS

We explore one synthetic dataset, to build intuition and confirm parameter recovery, and five large scale applications of IRT to real world data, summarized in Table 1.

Table 1: Dataset Statistics

	# PERSONS	# ITEMS	MISSING DATA?
CRITLANGACQ	669498	95	N
WORDBANK	5520	797	N
DUOLINGO	2587	2125	Y
GRADESCOPE	1254	98	Y
PISA	519334	183	Y

Synthetic IRT To sanity check that VIBO performs as well as other inference techniques, we synthetically generate a dataset of responses using a 2PL IRT model: sample $\mathbf{a}_i \sim p(\mathbf{a}_i)$, $\mathbf{d}_j \sim p(\mathbf{d}_j)$. Given ability and item characteristics, IRT-2PL determines a Bernoulli distribution over responses to item j by person i . We sample once from this Bernoulli distribution to “generate” an observation. In this setting, we know the ground truth ability and item characteristics. We vary N and M to explore parameter recovery.

Second Language Acquisition This dataset contains native and non-native English speakers answering questions to a grammar quiz³, which upon completion would return a prediction of the user’s native language. Using social media, over half a million users of varying ages and demographics completed the quiz. Quiz questions often contain both visual and linguistic components. For instance, a quiz question could ask the user to “choose the image where the dog is chased by the cat” and present two images of animals where only one of image agrees with the caption. Every response is thus binary, marked as correct or incorrect. In total, there are 669,498 people with 95 items and no missing data. The creators of this dataset use it to study the presence or absence of a “critical period” for second language acquisition [19]. We will refer to this dataset as CRITLANGACQ.

WordBank: Vocabulary Development The MacArthur-Bates Communicative Development Inventories (CDIs) are a widely used metric for early language acquisition in children, testing concepts in vocabulary comprehension, production, gestures, and grammar. The WordBank [14] database archives many independently collected CDI datasets across languages and research laboratories⁴. The database consists of a matrix of people against vocabulary words where the (i, j) entry is 1 if a parent reports that child i has knowledge of word j and 0 otherwise. Some entries are missing due to slight variations in surveys and incomplete responses. In total, there are 5,520 children responding to 797 items.

³The quiz can be found at www.gameswithwords.org. The data is publically available at osf.io/pyb8s.

⁴github.com/langcog/wordbankr

DuoLingo: App-Based Language Learning We examine the 2018 DuoLingo Shared Task on Second Language Acquisition Modeling⁵ [38]. This dataset contains anonymized user data from the popular education application, DuoLingo. In the application, users must choose the correct vocabulary word among a list of distractor words. We focus on the subset of native English speakers learning Spanish and only consider lesson sessions. Each user has a timeseries of responses to a list of vocabulary words, each of which is shown several times. We repurpose this dataset for IRT: the goal being to infer the user’s language proficiency from his or her errors. As such, we average over all times a user has seen each vocabulary item. For example, if the user was presented “habla” 10 times and correctly identified the word 5 times, he or she would be given a response score of 0.5. We then round to 0 or 1. We revisit a continuous version Sec. 7. After processing, we have 2587 users and 2125 vocabulary words with missing data as users frequently drop out. We ignore user and syntax features.

Gradescope: Course Exam Data Gradescope [39] is a course application that assists teachers in grading student assignments. This dataset contains 105,218 responses from 6,607 assignments in 2,748 courses and 139 schools. All assignments are instructor-uploaded, fixed-template assignments, with at least 3 questions, with the majority being examinations. We focus on course 102576, randomly chosen. We remove students who did not respond to any questions and round up partial credit. In total, there are 1254 students with 98 items, with missing entries.

PISA 2015: International Assessment The Programme for International Student Assessment (PISA) is an international exam that measures 15-year-old students’ reading, mathematics, and science literacy every three years. It is run by the Organization for Economic Cooperation and Development (OECD). The OECD released anonymized data from PISA ’15 for students from 80 countries and education systems⁶. We focus on the science component. Using IRT to access student performance is part of the pipeline the OECD uses to compute holistic literacy scores for different countries. As part of our processing, we binarize responses, rounding any partial credit to 1. In total, there are 519,334 students and 183 questions. Not every student answers every question as many versions of the computer exam exist.

5. FAST AND ACCURATE INFERENCE

We will show that VIBO is as accurate as HMC and nearly as fast as MLE/EM, making Bayesian IRT a realistic, even preferred, option for modern applications.

5.1 Evaluation

We compare compute cost of VIBO to HMC, EM⁷, and MLE using IRT-2PL by measuring wall-clock run time. For HMC, we limit to drawing 200 samples with 100 warmup steps with no parallelization. For VIBO and MLE, we use the Adam optimizer with a learning rate of 5e-3. We choose to conservatively optimize for 10k iterations to estimate cost.

⁵sharedtask.duolingo.com/2018.html

⁶oecd.org/pisa/data/2015database

⁷We use the popular MIRT package in R for EM with 61 points for numerical integration.

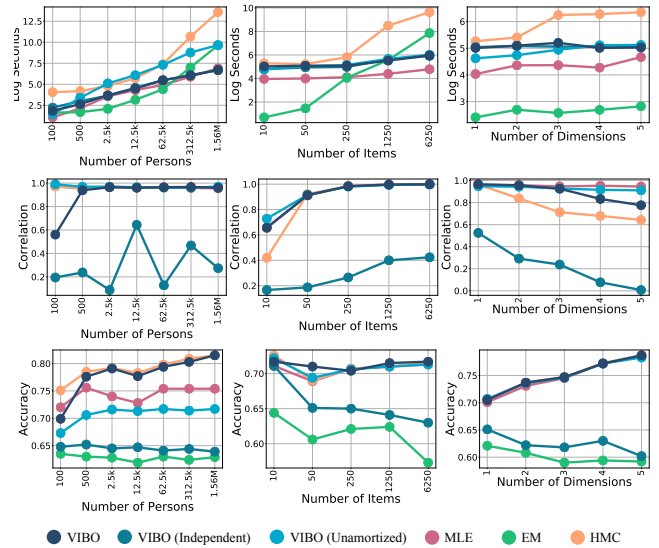

Figure 2: Performance of inference algorithms for IRT for synthetic data, as we vary the number of people, items, and latent ability dimensions. (Top) Computational cost in log-seconds (e.g. 1 log second is about 3 seconds whereas 10 log seconds is 6.1 hours). (Middle) Correlation of inferred ability with true ability (used to generate the data). (Bottom) Accuracy of held-out data imputation.

However, speed only matters assuming good performance. We use three metrics of accuracy: (1) For the synthetic dataset, because we know the true ability, we can measure the expected correlation between it and the inferred ability under each algorithm (with the exception of EM as ability is not inferred). A correlation of 1.0 would indicate perfect inference. (2) The most general metric is the accuracy of imputed missing data. We hold out 10% of the responses, use the inferred ability and item characteristics to generate responses thereby populating missing entries, and compute prediction accuracy for held-out responses. This metric is a good test of “overfitting” to observed responses. (3) In the case of fully Bayesian methods (HMC and VIBO) we can compare posterior predictive statistics [40] to further test uncertainty calibration (which accuracy alone does not capture). Recall that the posterior predictive is defined as:

$$p(\tilde{\mathbf{r}}_{i,1:M} | \mathbf{r}_{i,1:M}) = \mathbb{E}_{p(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})} [p(\tilde{\mathbf{r}}_{i,1:M} | \mathbf{a}_i, \mathbf{d}_{1:M})]$$

For HMC, we have samples of ability and item characteristics from the true posterior whereas for VIBO, we draw samples from the $q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})$. Given such parameter samples, we can then sample responses. We compare summary statistics of these response samples: the average number of items answered correctly per person and the average number of people who answered each item correctly.

5.2 Synthetic Data Results

With synthetic experiments we are free to vary N and M to extremes to stress test the inference algorithms: first, we range from 100 to 1.5 million people, fixing the number of items to 100 with dimensionality 1; second, we range from 10 to 6k items, fixing 10k people with dimensionality 1; third, we vary the number of latent ability dimensions from 1 to 5, keeping a constant 10k people and 100 items.

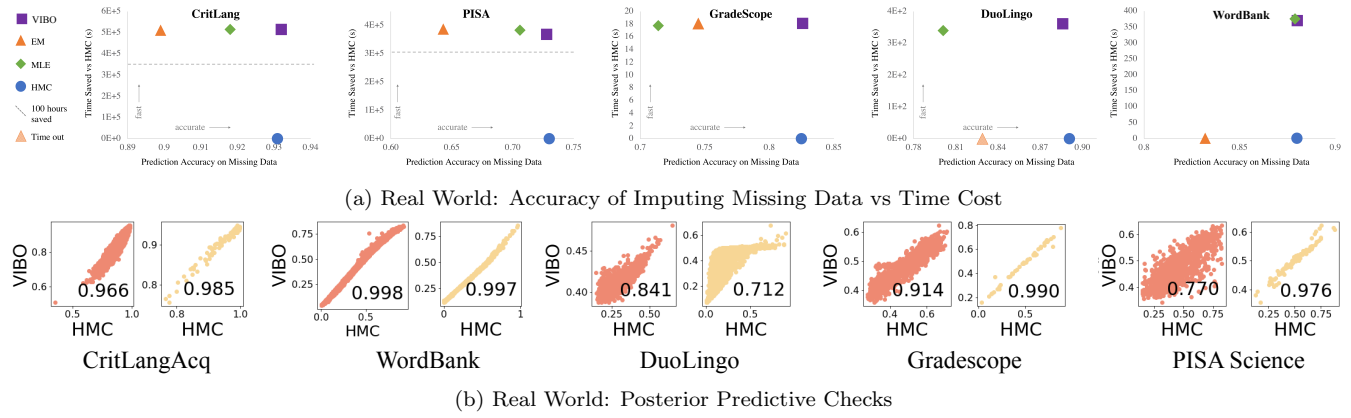

Figure 3: (a) Accuracy of missing data imputation for real world datasets plotted against time saved in seconds compared to using HMC. (b) Samples statistics from the predictive posterior defined using HMC and VIBO. A correlation of 1.0 would be perfect alignment between two inference techniques. Subfigures in red show the average number of items answered correctly for each person. Subfigures in yellow show the average number of people who answered each item correctly.

Fig. 2 shows run-time and performance results for VIBO, MLE, HMC, EM, and two ablations of VIBO (discussed in Sec. 5.4). First, comparing parameter recovery performance (Fig. 2 middle), we see that HMC, MLE and VIBO all recover parameters well. The only notable differences are: VIBO with very few people, and HMC and (to a lesser extent) VIBO in high dimensions. The former is because the amortized posterior approximation requires a sufficiently large dataset (around 500 people) to constrain its parameters. The latter is a simple effect of the scaling of variance for sample-based estimates as dimensionality increases (we fixed the number of samples used, to ease speed comparisons).

Turning to the ability to predict missing data (Fig. 2 bottom) we see that VIBO performs equally well to HMC, except in the case of very few people (again, discussed below). (Note that the latent dimensionality does not adversely affect VIBO or HMC for missing data prediction, because the variance is marginalized away.) MLE also performs well as we scale number of items and latent ability dimensions, but is less able to benefit from more people. EM on the other hand provides much worse missing data prediction in all cases.

Finally if we examine the speed of inference (Fig. 2 top), VIBO is only slightly slower than MLE, both of which are orders of magnitude faster than HMC. For instance, with 1.56 million people, HMC takes 217 hours whereas VIBO takes 800 seconds. Similarly with 6250 items, HMC takes 4.3 hours whereas VIBO takes 385 seconds. EM is the fastest for low to medium sized datasets, though its lower accuracy makes this a dubious victory. Furthermore, EM does not scale as well as VIBO to large datasets.

5.3 Real World Data Results

We next apply VIBO to real world datasets in cognitive science and education. Fig. 3(a) plots the accuracy of imputing missing data against the time saved vs HMC (the most expensive inference algorithm) for five large-scale datasets. Points in the upper right corner are more desirable as they are more accurate and faster. The dotted line represents 100 hours saved compared to HMC.

From Fig. 3(a), we find many of the same patterns as we observed in the synthetic experiments. Running HMC on CritLangAcq or PISA takes roughly 120 hours whereas VIBO takes 50 minutes for CritLangAcq and 5 hours for PISA, the latter being more expensive because of computation required for missing data. In comparison, EM is at times faster than VIBO (e.g. Gradescope, PISA) and at times slower. With respect to accuracy, VIBO and HMC are again identical, outperforming EM by up to 8% in missing data imputation. Interestingly, we find the “overfitting” of MLE to be more pronounced here. If we focus on DuoLingo and Gradescope, the two datasets with pre-existing large portions of missing values, MLE is surpassed by EM, with VIBO achieving accuracies 10% higher.

Another way of exploring a model’s ability to explain data, for fully Bayesian models, is posterior predictive checks. Fig. 3(b) shows posterior predictive checks comparing VIBO and HMC. We find that the two algorithms strongly agree about the average number of correct people and items in all datasets. The only systematic deviations occur with DuoLingo: it is possible that this is a case where a more expressive posterior approximation would be useful in VIBO, since the number of items is greater than the number of people.

5.4 Ablation Studies

We compared VIBO to simpler variants that either do not amortize the posterior or do so with independent distributions of ability and item parameters. These correspond to different variational families, \mathcal{Q} to choose q from:

- VIBO (Independent): We consider the decomposition $q(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M}) = q(\mathbf{a}_i | \mathbf{r}_{i,1:M}) q(\mathbf{d}_{1:M})$ which treats ability and item characteristics as independent.
- VIBO (Unamortized): We consider $q(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M}) = q_{\psi(\mathbf{r}_{i,1:M})}(\mathbf{a}_i) q(\mathbf{d}_{1:M})$, which learns separate posteriors for each \mathbf{a}_i , without parameter sharing. Recall the subscripts $\psi(\mathbf{r}_{i,1:M})$ indicate a separate variational posterior for each unique set of responses.

If we compare unamortized to amortized VIBO in Fig. 2 (top), we see an important efficiency difference. The number

of parameters for the unamortized version scales with the number of people; the speed shows a corresponding impact, with the amortized version becoming an order of magnitude faster than the unamortized one. In general, amortized inference is much cheaper, especially in circumstances in which the number of possible response vectors $\mathbf{r}_{1:M}$ is very large (e.g. 2^{95} for CritLangAcq). Comparing amortized VIBO to the un-amortized equivalent, Table 2 compares the wall clock time (sec.) for the 5 real world datasets. While VIBO is comparable to MLE and EM (Fig. 3a), unamortized VIBO is 2 to 15 times more expensive.

Exploring accuracy in Fig. 2 (bottom), we see that the un-amortized variant is significantly less accurate at predicting missing data. This can be attributed to overfitting to observed responses. With 100 items, there are 2^{100} possible responses from every person, meaning that even large datasets only cover a small portion of the full set. With amortization, overfitting is more difficult as the deterministic mapping f_ϕ is not hardcoded to a single response vector. Without amortization, since we learn a variational posterior for every observed response vector, we may not generalize to new response vectors. Unamortized VIBO is thus much more sensitive to missing data as it does not get to observed the entire response. We can see evidence of this as unamortized VIBO is superior to amortized VIBO at parameter recovery, Fig. 2 (middle), where no data is hidden from the model; compare this to missing data imputation, where unamortized VIBO appears inferior: because ability estimates do not share parameters, those with missing data are less constrained yielding poorer predictive performance.

Finally, when there are very few people (100) unamortized VIBO and HMC are better at recovering parameters (Fig. 2 middle) than amortized VIBO. This can be explained by amortization: to train an effective regressor f_ϕ requires a minimum amount of data. With too few responses, the amortization gap will be very large, leading to poor inference. Under scarce data we would thus recommend using HMC, which is fast enough and most accurate.

Table 2: Time Costs with and without Amortization

DATASET	AMORTIZED (SEC.)	UN-AMORTIZED (SEC.)
CRITLANGACQ	2.8K	43.2K
WORDBANK	176.4	657.1
DUOLINGO	429.9	717.9
GRADESCOPE	114.5	511.1
PISA	25.2K	125.8K

The above suggests that amortization is important when dealing with moderate to large datasets. Turning to the structure of the amortized posteriors, we note that the factorization we chose in Thm. 3.1 is only one of many. Specifically, we could make the simpler assumption of independence between ability and item characteristics given responses in our variational posteriors: VIBO (Independent). Such a factorization would be simpler and faster due to less gradient computation. However, in our synthetic experiments (in which we know the true ability and item features), we found the independence assumption to produce very poor results: recovered ability and item characteristics had less than 0.1 correlation with the true parameters. Meanwhile

the factorization we posed in Thm. 3.1 consistently produced above 0.9 correlation. Thus, the insight to decompose $q(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M}) = q(\mathbf{a}_i | \mathbf{d}_{1:M}, \mathbf{r}_{i,1:M}) q(\mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})$ instead of assuming independence is a critical one. (This point is also supported theoretically by research on faithful inversions of graphical models [43].)

6. DEEP ITEM RESPONSE THEORY

We have found VIBO to be fast and accurate for inference in 2PL IRT, matching HMC in accuracy and EM in speed. This classic IRT model is a surprisingly good model for item responses despite its simplicity. Yet it makes strong assumptions about the interaction of factors, which may not capture the nuances of human cognition. With the advent of much larger data sets we have the opportunity to explore corrections to classic IRT models, by introducing more flexible non-linearities. As described above, a virtue of VI is the possibility of learning aspects of the generative model by optimizing the inference objective. We next explore several ways to incorporate learnable non-linearities in IRT, using the modern machinery of deep learning.

6.1 Nonlinear Generalizations of IRT

We have assumed thus far that $p(\mathbf{r}_{i,1:M} | \mathbf{a}_i, \mathbf{d}_{1:M})$ is a fixed IRT model defining the probability of correct response to each item. We now consider three different alternatives with varying levels of expressivity that help define a class of more powerful nonlinear IRT.

Learning a Linking Function We replace the logistic function in standard IRT with a nonlinear linking function. As such, it preserves the linear relationships between items and people. We call this VIBO (Link). For person i and item j , the 2PL-Link generative model is:

$$p(r_{ij} | \mathbf{a}_i, \mathbf{d}_j) = f_\theta(-\mathbf{a}_i^T \mathbf{k}_j - \mathbf{d}_j) \quad (16)$$

where f_θ is a one-dimensional nonlinear function followed by a sigmoid to constrain the output to be within $[0, 1]$. In practice, we parameterize f_θ as a multilayer perceptron (MLP) with three layers of 64 hidden nodes with ELU nonlinearities.

Learning a Neural Network Here, we no longer preserve the linear relationships between items and people and instead feed the ability and item characteristics directly into a neural network, which will combine the inputs nonlinearly. We call this version VIBO (Deep). For person i and item j , the Deep generative model is:

$$p(r_{ij} | \mathbf{a}_i, \mathbf{d}_j) = f_\theta(\mathbf{a}_i, \mathbf{d}_j) \quad (17)$$

where again f_θ includes a Sigmoid function at the end to preserve the correct output signatures. This is an even more expressive model than VIBO (Link). In practice, we parameterize f_θ as three MLPs, each with 3 layers of 64 nodes and ELU nonlinearities. The first MLP maps ability to a real vector; the second maps item characteristics to a real vector. These two hidden vectors are concatenated and given to the final MLP, which predicts response.

Learning a Residual Correction Although clearly a powerful model, we might fear that VIBO (Deep) becomes too uninterpretable. So, for the third and final nonlinear model, we use the standard IRT but add a nonlinear residual

component that can correct for any inaccuracies. We call this version VIBO (Residual). For person i and item j , the 2PL-Residual generative model is:

$$p(r_{ij}|\mathbf{a}_i, \mathbf{k}_j, d_j) = \frac{1}{1 + e^{-\mathbf{a}_i^T \mathbf{k}_j - d_j + f_\theta(\mathbf{a}_i, \mathbf{k}_j, d_j)}} \quad (18)$$

During optimization, we initialize the weights of the residual network to 0, thus ensuring its initial output is 0. This encourages the model to stay close to IRT, using the residual only when necessary. We use the same architectures for the residual component as in VIBO (Deep).

6.2 Nonlinear IRT Evaluation

A generative model explains the data better when it assigns observations higher probability. We thus evaluate generative models by estimating the log marginal likelihood $\log p(\mathbf{r}_{1:N,1:M})$ of the training dataset. A higher number (closer to 0) is better. For a single person, the log marginal likelihood of his or her M responses can be computed as:

$$\log p(\mathbf{r}_{i,1:M}) \approx \log \mathbb{E}_{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})} \left[\frac{p_\theta(\mathbf{r}_{i,1:M}, \mathbf{a}_i, \mathbf{d}_{1:M})}{q_\phi(\mathbf{a}_i, \mathbf{d}_{1:M} | \mathbf{r}_{i,1:M})} \right] \quad (19)$$

We use 1000 samples to estimate Eq. 19. We also measure accuracy on missing data imputation as we did in Sec. 5. A more powerful generative model, that is more descriptive of the data, should be better at filling in missing values.

6.3 Nonlinear IRT Results

The top half of Table 3 compares the log likelihoods of observed data whereas the bottom half of Table 3 compares the accuracy of imputing missing data. We include VIBO inference with classical IRT-1PL and IRT-2PL generative models as baselines. We find a consistent trend: the more powerful generative models achieve a higher log likelihood (closer to 0) and a higher accuracy. In particular, we find very large increases in log likelihood moving from IRT to Link, spanning 100 to 500 log points depending on the dataset. Further, from Link to Deep and Residual, we find another increase of 100 to 200 log points. In some cases, we find Residual to outperform Deep, though the two are equally parameterized, suggesting that initialization with IRT can find better local optima. These gains in log likelihood translate to a consistent 1 to 2% increase in held-out accuracy for Link/Deep/Residual over IRT. This suggests that the datasets are large enough to use the added model flexibility appropriately, rather than overfitting to the data.

We also compare our deep generative IRT models with the purely deep learning approach called Deep-IRT [47] (see Sec. 8), that does not model posterior uncertainty. Unlike traditional IRT models, Deep-IRT was built for knowledge tracing and assumed sequential responses. To make our datasets amenable to Deep-IRT, we assume an ordering of responses from $j = 1$ to $j = M$. As shown in Table 3, our models outperform Deep-IRT in all 5 datasets by as much as 30% in missing data imputation (e.g. WordBank).

6.4 Interpreting the Linking Function

With nonlinear models, we face an unfortunate tradeoff between interpretability and expressivity. In domains like education, practitioners greatly value the interpretability of IRT where predictions can be directly attributed to ability

or item features. With VIBO (Deep), our most expressive model, predictions use a neural network, making it hard to understand the interactions between people and items.

Figure 4: Learned link functions for (a) CritLangAcq, (b) WordBank, (c) DuoLingo, (d) Gradescope, and (e) PISA. The dotted black line shows the default logistic function.

Fortunately, with VIBO (Link), we can maintain a degree of interpretability along with power. The “Link” generative model is identical to IRT, only differing in the linking function (i.e. item response function). Each subfigure in Fig. 4 shows the learned response function for one of the real world datasets; the dotted black line represents the best standard linking function, a sigmoid. We find three classes of linking functions: (1) for Gradescope and PISA, the learned function stays near a Sigmoid. (2) For WordBank and CritLangAcq, the response function closely resembles an unfolding model [27, 2], which encodes a more nuanced interaction between ability and item characteristics: higher scores are related to higher ability only if the ability and item characteristics are “nearby” in latent space. (3) For DuoLingo, we find a piecewise function that resembles a sigmoid for positive values and a negative linear function for negative values. In cases (2) and (3) we find much greater differences in log likelihood between VIBO (IRT) and VIBO (Link). See Table 3. For DuoLingo, VIBO (Link) matches the log density of more expressive models, suggesting that most of the benefit of nonlinearity is exactly in this unusual linking function.

7. POLYTOMOUS RESPONSES

Thus far, we have been working only with response data collapsed into binary correct/incorrect responses. However, many questionnaires and examinations are not binary: responses can be multiple choice (e.g. Likert scale) or even real valued (e.g. 92% on a course test). Having posed IRT as a generative model, we have prescribed a Bernoulli distribution over the i -th person’s response to the j -th item. Yet nothing prevents us from choosing a different distribution, such as Categorical for multiple choice or Normal for real-values. The DuoLingo dataset contains partial credit, computed as a fraction of times an individual gets a word correct. A more granular treatment of these polytomous values should yield a more faithful model that can better capture the differences between people. We thus modeled the DuoLingo data using for $p(\mathbf{r}_{i,1:M}|\mathbf{a}_i, \mathbf{d}_{1:M})$ a (truncated) Normal distribution over responses with fixed variance. Table 4 show the log densities: we again observe large improvements from nonlinear models.

Item Response Theory can in this way be extended to work of all kinds (imagine students writing text, drawing pictures, or even coding), encouraging educators to assign open-ended work without having to give up proper tools of assessment.

We described above a variety of methods for parameter estimation in IRT such as MLE, EM, and MCMC. The benefits and drawbacks of these methods are well-documented [26], so we need not discuss them here. Instead, we focus specifically on methods that utilize deep neural networks or variational inference to estimate IRT parameters.

While variational inference has been suggested as a promising alternative to other inference approaches for IRT [26], there has been surprisingly little work in this area. In an exploration of Bayesian prior choice for IRT estimation, Natesan et al. [31] posed a variational approximation to the posterior:

$$p(\mathbf{a}_i, \mathbf{d}_j | r_{i,j}) \approx q_\phi(\mathbf{a}_i, \mathbf{d}_j) = q_\phi(\mathbf{a}_i)q_\phi(\mathbf{d}_j) \quad (20)$$

This is an unamortized and independent posterior family, unlike VIBO. As we noted in Sec. 5.4, both amortization and dependence of ability on items were crucial for our results.

We are aware of two approaches that incorporate deep neural networks into Item Response Theory: Deep-IRT [46] and DIRT [8]. Deep-IRT is a modification of the Dynamic Key-Value Memory Network (DKVMN) [47] that treats data as longitudinal, processing items one-at-a-time using a recurrent architecture. Deep-IRT produces point estimates of ability and item difficulty at each time step, which are then passed into a 1PL IRT function to produce the probability of answering the item correctly. The main difference between DIRT and Deep-IRT is the choice of neural network: instead of the DKVMN, DIRT uses an LSTM with attention [41]. In our experiments, we compare our approach to Deep-IRT and find that we outperform it by up to 30% on the accuracy of missing response imputation. On the other hand, our models do not capture the longitudinal aspect of response data. Combining the two approaches would be natural.

Lastly, Curi et al. [9] used a VAE to estimate IRT parameters in a 28-question synthetic dataset. However, this approach modeled ability as the only unknown variable, ignoring items. Our analogue to the VAE builds on the IRT graphical model,

incorporating both ability and item characteristics in a principled manner. This could explain why Curi et. al. report the VAE requiring substantially more data to recover the true parameters when compared to MCMC whereas we find comparable data-efficiency between VIBO and MCMC.

9. BROADER IMPACT

We briefly emphasize the broader impact of efficient IRT in the context of education. Firstly, one of the many difficulties of accurately estimating student ability is cost: attempting to use MCMC on the order magnitude required by large entities like MOOCs, local and national governments, and international organizations is impossible. However with VIBO, doing so is already possible, as shown by the PISA results. Second, efficient IRT is an important and necessary step to encourage the development of more complex models of student cognition and response. Namely, it will at least enable faster research and iterative testing on real world data.

10. CONCLUSION

Item Response Theory is a paradigm for reasoning about the scoring of tests, surveys, and similar measurement instruments. Notably, the theory plays an important role in education, medicine, and psychology. Inferring ability and item characteristics poses a technical challenge: balancing efficiency against accuracy. In this paper we have found that variational inference provides a potential solution, running orders of magnitude faster than MCMC algorithms while matching their state-of-the-art accuracy.

Many directions for future work suggest themselves. First, further gains in speed and accuracy could be found by exploring more or less complex families of posterior approximation. Second, more work is needed to understand deep generative IRT models and determine the most appropriate tradeoff between expressivity and interpretability. For instance, we found significant improvements from a learned linking function, yet in some applications monotonicity may be judged important to maintain – greater ability, for instance, should correspond to greater chance of success. Finally, VIBO should enable more coherent, fully Bayesian, exploration of very large and important datasets, such as PISA [13].

Recent advances within AI combined with new massive datasets have enabled advances in many domains. We have given an example of this fruitful interaction for understanding humans based on their answers to questions.

ABSTRACT

In the learning sciences, heterogeneity among students usually leads to different learning strategies or patterns and may require different types of instructional interventions. Therefore, it is important to investigate student subtyping, which is to group students into subtypes based on their learning patterns. Subtyping from complex student learning processes is often challenging because of the information heterogeneity and temporal dynamics. Various inverse reinforcement learning (IRL) algorithms have been successfully employed in many domains for inducing policies from the trajectories and recently has been applied for analyzing students' temporal logs to identify their domain knowledge patterns. IRL was originally designed to model the data by assuming that all trajectories have a *single* pattern or strategy. Due to the heterogeneity among students, their strategies can vary greatly and the design of traditional IRL may lead to suboptimal performance. In this paper, we applied a novel expectation-maximization IRL (EM-IRL) to extract heterogeneous learning strategies from sequential data collected from three simulation environments and real-world longitudinal students' logs. Experiments on simulation environments showed that EM-IRL can successfully identify different policies from the heterogeneous sequences with different strategies. Furthermore, experimental results from our educational dataset showed that EM-IRL can be used to obtain different student subtypes: a *"learning-oriented"* subtype who learned the material as much as possible regardless of the time in that they spent significantly more time than the other two subtypes and learned significantly; an *"efficient-oriented"* subtype who learned efficiently in that they not only learned significantly but also spent less time than the first subtype; a *"no learning"* subtype who spent less amount of time than first subtype and failed to learn.

Subtyping, learning progression modeling, Student strategy, Inverse reinforcement learning

1. INTRODUCTION

With the rapid development of educational technologies, longitudinal students' learning progression trajectories are readily available. It is often challenging to analyze large-scale heterogeneous progression trajectories to infer high-level information embedded in student subgroups. This challenge motivates the development of student modeling [1, 2, 3, 4] and instructional intervention [5, 6, 7, 8].

Student subtyping, which seeks student groups with similar learning progression trajectories, is crucial to address the heterogeneity in the students, which ultimately leads to personalized instruction where students are provided with interventions tailored to their unique learning status. Student subtyping facilitates the investigation of different types of pedagogical strategies. From the data mining perspective, student subtyping is posed as an unsupervised clustering task of grouping students according to their historical records. Since these records are longitudinal and interrelated, it is important to capture the dependencies among the elements of the recorded sequence to learn more effective and robust representations, which can be utilized in the clustering stage to obtain the student subgroups.

This work aims at investigating *student subtyping* based on their pedagogical strategies, which can be seen as a process of self-regulated learning [9, 10, 11, 12, 13] by setting one's learning goals and ensuring the goals to be attained. Specifically, we focus on students' pedagogical decision-making strategies during their interactions with an intelligent tutoring system (ITS) to learn the probability. In this ITS, once a problem is presented, the students will decide whether they want the ITS *to tell* them how to solve the next problem or complete the next step, by presenting a worked example, or they want the ITS *to elicit* the next problem or take the next step themselves, by requiring problem solving. When making pedagogical decisions, the students have to self-regulate their own learning process which may change the learning outcomes even though the instructional content is controlled. We believe that students' pedagogical strategies are closely related to metacognition, i.e., the processes involved in thinking about thinking [14].

Reinforcement learning (RL) offers one of the most promising approaches to induce effective pedagogical strategies directly from data. A number of researchers have studied applying RL to improve the effectiveness of ITSs, e.g. [15, 7, 16, 17, 18, 19, 20, 8, 21, 22], and much of the prior work fo-

Xi Yang, Guojing Zhou, Michelle Taub, Roger Azevedo and Min Chi "Student Subtyping via EM-Inverse Reinforcement Learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 269 - 279

cused on inducing effective policies that determine the best action for the *ITS* to take in any given situation so as to maximize a cumulative reward, which is often the student learning gain. On the other hand, in this work, our goal is to infer *students'* pedagogical strategies based on their behaviors and decisions while interacting with the ITS.

To do so, we applied *inverse reinforcement learning (IRL)*. Unlike RL, where the reward function is explicitly given as input, IRL takes a bunch of trajectories as input and from which a reward function will be inferred. Given this inferred reward function, the RL can be further deployed to induce the decision-making policy. Since the students' decisions are generally made based on a trade-off among various complex factors, e.g., time, learning gain, difficulty of problems, etc., merely taking the learning gain as the reward cannot reflect the actual decision-making patterns. As a result, we employed IRL to learn students' strategies based on their behavioural data. Recently, IRL has been widely employed in various domains to understand how decisions are made in the given trajectories [23, 24]. Specifically, it has been employed in educational domains to analyze students' temporal log data to identify their domain knowledge patterns [25, 26]. However, IRL was originally designed to model the data by assuming that all trajectories share a *single* pattern or strategy. Considering the heterogeneity among students, their pedagogical strategies can vary greatly and the design of traditional IRL may lead to suboptimal performance. Though we can apply IRL individually for each student, it will forfeit our goal of revealing some general and meaningful patterns from students' trajectories in consideration of the heterogeneity among subgroups of students.

We employed a novel expectation-maximization IRL (EM-IRL) algorithm [27] to model the heterogeneity among student subtypes by assuming that different student subtypes have different pedagogical strategies and students within each subtype share the same strategy. The EM-IRL would recursively cluster students into different subgroups and induce a policy for each group by IRL until both clusters and policies get converged. In the original EM-IRL work, it requires the number of clusters to be pre-defined [27]. However, when applying it to student subtyping in education, it is often hard to figure out beforehand how many types of strategies are involved in students' trajectories. Therefore, we embedded the original EM-IRL into a general framework which can automatically determine the optimal number of clusters from the data.

In this work, we evaluated our general framework on three simulation environments: Grid World, Highway, and Mountain Car, and on real-world longitudinal students' logs collected from an ITS. Our results in three simulation environments showed that EM-IRL could accurately cluster the data with different decision-making strategies. In addition, the experimental results showed that EM-IRL could be easily employed to obtain the student subtypes. Specifically, we got three student subtypes: a "*learning-oriented*" subtype who try to learn the material as much as possible regardless of the time spent and they learned significantly from pre- to post-test; an "*efficient-oriented*" subtype who learn efficiently in that they not only learned significantly but also spent significantly less time than the first subtype; a "*no*

learning" subtype who spent the less time and failed to learn. The clustering results suggested the potential of targeting the students who are not using effective pedagogical strategies, adapting the interventions, and offering the students effective pedagogical skill training through the ITS.

The remaining parts are organized as follows. In Section 2, related works are reviewed. Section 3 presents the methods, including the RL, IRL, and EM-IRL. Section 4 displays preliminary results we got in three simulation environments. Section 5 details data collected from the ITS. In Section 6, we discuss the experimental setup for EM-IRL and some other clustering methods. Section 7 presents the experimental results. Finally, Section 8 summarizes the paper.

2. RELATED WORKS

2.1 Students' Subtyping

Previous research has widely explored modeling of student subtyping to assist teachers in providing more targeted interventions at the right time. Generally, student subtyping was analyzed via unsupervised clustering methods. For example, Lopez et al. employed an expectation maximisation clustering method to determine if the students' participation in course Moodle forum could be a good predictor of the final marks [28]. Durairaj and Vijitha applied K-means clustering to predict the pass/fail percentage of the students who appeared for a particular examination [29]. Khalil and Ebner clustered the students into appropriate categories based on their level of engagement [30], so that the teachers could increase retention and improve interventions for specific sub-population. All of these methods were based on the static data, without considering the dynamic properties during learning.

With the rapid development of e-learning, an increasing amount of sequential data was collected via ITSs. In general, the clustering methods to handle sequential data could be generalized into three categories: proximity-based, feature-based, and model-based [31]. More specifically, proximity-based methods measures the similarity between the pair-wise data via the distance calculated by the longest common subsequence, dynamic time warping, etc. For example, Shen and Chi proposed a temporal clustering framework which measured pair-wise distance between the students by dynamic time warping and then clustered them by hierarchical clustering [32]. Their method identified some distinctive patterns among the clusters, which could provide benefits to the personalized learning. Feature-based approaches would first compress the sequential data to be static, then the clustering methods taking static data as input could be further employed. For example, in [33] and [34], the authors aggregated the students' activities to a feature vector and then applied K-means clustering to recognize learner groups in exploratory learning environments. In the model-based methods, the similarity of two data could be calculated based on the likelihood of one of them given the model derived from the other. For example, Li and Yoo proposed to use a Markov chain based clustering methodology to model the students' online learning behaviors collected during the learning process for more effective and adaptive teaching [31]. Additionally, Kock and Paramythis proposed a method combining K-means clustering with dis-

crete Markov models to identify new, semantically meaningful problem-solving styles of the learners [35].

2.2 Students' Pedagogical Strategies

A number of researchers have investigated students' pedagogical decision-making [36, 37, 38, 39, 40, 41]. Previous research has shown that students make pedagogical decisions strategically. For example, Aleven et al. conducted a study to investigate students' hint usage behavior [36]. Results showed that students used the easy-to-apply intelligent help more often than the Glossary. However, students often waited long before asking for a hint. When requesting hints, they often skipped the intermediate hints to reach the bottom-out hint which showed the solution directly. The results suggested that students preferred less effort-taking help (intelligent help and bottom-out hint), and oftentimes, they used the help less than they needed.

Additionally, prior research showed that providing students with pedagogical decision-making assistance could result in better decision-making skills or learning performance. Roll et al. [37] examined the relationship between students' help-seeking patterns and learning performance. They found that asking for help on challenging steps was generally productive while help abusing behaviors were correlated with poor learning. Mitrovic et al. [38] compared three types of decision-making modes: system control, student control, and faded control. Under the faded control, the system selected the problem for the student at the beginning of the training and gave explanations of why the problems should be selected. As the training proceeded, the control was given to the students. Results showed that the faded control group demonstrated improved problem selection skill and achieved better learning gain than the other two groups. Long et al. [39] compared an assistance condition, where problem selection assistance was provided, with standard condition (no assistance). Their results showed the assistance condition achieved significantly better learning performance and better declarative knowledge of a key problem-selection strategy comparing to the standard condition.

2.3 Learning From Demonstrations

Learning from demonstrations [42], also known as imitation learning [43] or apprenticeship learning [44], is a process to reproduce the decision-making behaviors in demonstrated trajectories. Generally, the methods in this area can be categorized into two groups: 1) directly learning a policy as a state-action mapping by parroting the demonstrated behaviors, which is typically done via supervised learning; and 2) inferring rewards from the demonstrations and then applying reinforcement learning (RL) to induce the policy, which is called inverse reinforcement learning (IRL). The latter is generally preferred because the reward is a more robust, succinct, and transferable definition for a task [45]. Specifically, comparing to supervised learning, IRL has higher generalization ability to robustly learn from smaller size trajectories collected from larger state spaces, and the succinctly represented reward function can be handily transferred to other agents in different scenarios.

Based on how the rewards are inferred, existing IRL algorithms can be generalized into two categories: maximum margin-based methods and probabilistic model-based meth-

ods. Specifically, maximum margin-based methods infer rewards by finding a model to maximize the margin between the demonstrated trajectories and other alternative behaviors [44]. However, it is often suffers from the ill-posed issue with non-uniqueness [45], i.e., there can be multiple reward functions to explain the demonstrated behaviors. Probabilistic model-based methods, on the other hand, are able to handle this issue by using probability distributions to introduce preferences over reward functions [46]. In this category, Ramachandran and Amir [47] proposed a Bayesian IRL, which combined prior knowledge and evidence from the demonstrated trajectories to derive a probability distribution over the reward functions. Similarly, Ziebart et al. proposed a maximum entropy IRL which results in the least biased estimation of the reward function [23]. Babes-Vroman et al. [27] proposed a maximum likelihood IRL (MLIRL), which finds the reward function that maximize the probability to observe the demonstrated behaviors. Their experimental results showed that the MLIRL outperformed some other IRL methods, including the linear programming based maximum margin IRL and maximum entropy IRL.

All the above methods assume a *single* reward function for all demonstrations. Some other approaches have been proposed to handle the *multiple* reward functions. Dimitrakakis and Rothkopf [48] proposed a Bayesian multi-task IRL, which learns a reward function for each individual trajectory using the same prior distribution. Choi et al. [49] proposed a method based on nonparametric Bayesian IRL in which the prior of mixing distribution of different rewards was modeled by the Dirichlet process. Babes-Vroman et al. [27] proposed an EM-based framework, which iteratively computes the probabilities that the demonstrations belong to each cluster and updates the cluster-wise rewards based on MLIRL. Considering the efficiency and good performance EM-based method, we adapted it for analysis in this work.

Recently, IRL has been widely applied in various domains. Ziebart et al. [23] employed it in driver route modeling for predicting driving behaviors as well as for route recommendation. Asoh et al. [24] applied IRL to medical records and explored the potential rules in doctors' diagnosis. Of most relevance, IRL also showed effectiveness in educational domain. Rafferty et al. applied IRL in education applications to automatically infer learners' beliefs in an education game [25]. They demonstrated that IRL could recover the participant's beliefs towards how their actions could affect the environment, which indicated the potential to utilize IRL to interpret data from interactive educational environments. Then in another of their work, IRL was further employed to assess learners' mastery of some skills in solving algebraic equations. Based on the learned IRL results, some skills the learners misunderstood could be detected and personalized feedback for improving the skills were further rendered [26].

3. METHOD

3.1 Reinforcement Learning

Markov decision process (MDP) was widely utilized to model the user-system interactions. The central idea behind reinforcement learning (RL) is to transform the problem of inducing effective policies into a computational problem of finding an optimal policy for choosing actions in MDP. An

MDP describes a stochastic control process using a 5-tuple $\langle S, A, T, R, \gamma \rangle$. Taking the pedagogical policy induction as an example, S indicates the learning environment states, which is often represented by student-system interaction features. A denotes the tutor's possible actions, such as elicit or tell. The reward function R is generally assigned as students' learning performance. The transition probability T can be estimated from training data. $\gamma \in [0, 1)$ denotes a discount factor for the future rewards. Given a defined MDP, we can transform our student-system interaction logs into trajectories as: $s_1 \xrightarrow{a_1, r_1} s_2 \xrightarrow{a_2, r_2} \dots s_n \xrightarrow{a_n, r_n} s_{n+1}$. Here $s_i \xrightarrow{a_i, r_i} s_{i+1}$ indicates that at the i^{th} turn, the learning environment was in state s_i ; the tutor executed action a_i and received reward r_i ; then the environment transferred into the state s_{i+1} .

In traditional RL, the reward function R serves as a guidance to praise or punish the agent's behaviors to fulfil a certain task when interacting with the environment. Therefore, it is essential and needs to be elaborately hand-crafted in advance to reflect the task. In ITS, the reward is generally formulated as the students' learning performance, e.g., learning gains, since the intention of tutor's decision-making is to promote students' learning. However, the reward function in students' decision-making is more complex to be determined: students may have various learning patterns, e.g., finishing the process as quick as possible or working hard regardless of the time, which is cumbersome to be manually encoded in a reward function. The different reward functions reflected the different strategies students employed during the training process. Therefore, if student's reward function can be learned in a data-driven manner, we can better understand their pedagogical decision-making strategies.

3.2 Inverse Reinforcement Learning

3.2.1 General IRL

The difficulty of the reward function design triggered the development of the inverse reinforcement learning (IRL). IRL follows a reverse procedure comparing to the traditional RL: in RL, given the reward function, the agent will learn an optimal policy; while in IRL, the trajectories derived from the optimal policy are given, from which the agent will learn the reward function. It can be described as a stochastic control process using a 4-tuple $MDP \setminus R = \langle S, A, T, \gamma \rangle$ where the reward function is missing.

In general framework of IRL, the input is a $MDP \setminus R$ together with some demonstrated trajectories \mathcal{T} . The reward function \mathcal{R}_θ parameterized by θ can be modeled as either a linearly weighted sum of feature values or belonging to a certain distribution. Most of the existing IRL methods follow 3 steps: in step 1, the parameter θ is randomly initialized; in step 2, given the \mathcal{R}_θ , general RL methods can be applied to induce the policy; In step 3, the divergence of the behaviors regarding to the learned policy and the given trajectories is minimized to update the θ . The step 2 and step 3 are repeated until the divergence is reduced to a desired level.

To investigate students' pedagogical strategy, we can feed their decision-making trajectories into the IRL model. Once the reward function is learned, the strategy can be further induced via traditional RL methods. Herein, we compared some most commonly utilized IRL methods including: quadratic programming based maximum margin IRL [44],

General Process of IRL

Input $MDP \setminus R = \langle S, A, T, \gamma \rangle$ and trajectories \mathcal{T}

Output \mathcal{R}_θ

step 1 Initialize the parameter θ in reward function

step 2 Solve the MDP to learn the policy π

step 3 Update the optimization θ to minimize the divergence between \mathcal{T} and behaviors following the π

Repeat step 2 and step 3 until convergence

maximum entropy IRL [23], Bayesian IRL [47], and maximum likelihood IRL (MLIRL) [27] over three online simulation environments (i.e., Grid World, Highway, and Mountain Car). We found MLIRL always outperformed others and it is also most time-efficient. As a result, we take MLIRL for the IRL-based analysis hereinafter.

3.2.2 Maximum Likelihood IRL

To formally define the maximum likelihood IRL, we denote the input N demonstrated trajectories as $\mathcal{T} = \{\xi_1, \dots, \xi_N\}$ and each trajectory is composed of a set of state-action pairs: $\xi_i = \{(s_1, a_1), (s_2, a_2), \dots\}$. The reward function is defined as the linear function of feature vector for state-action pairs: $r_\theta(s, a) = \theta^T \phi(s, a)$. Then the Q-value can be calculated as:

$$Q_\theta(s, a) = \theta^T \phi(s, a) + \gamma \sum_{s'} T(s, a, s') \bigotimes_{a'} Q_\theta(s', a'), \quad (1)$$

$$\text{where } \bigotimes_a Q_\theta(s, a) = \frac{\sum_a Q_\theta(s, a) \exp(\beta Q_\theta(s, a))}{\sum_{a'} \exp(\beta Q_\theta(s, a'))} \quad (2)$$

Eq. 2 shows the Boltzmann exploration. Comparing to standard Bellman equation, it enables the likelihood to be differentiable, thus the objective function can be easier optimized. β represents the degree of confidence and it is set as 0.5 in our experiments. The Boltzmann exploration policy parameterized by θ is:

$$\pi_\theta(s, a) = \frac{\exp(\beta Q_\theta(s, a))}{\sum_{a'} \exp(\beta Q_\theta(s, a'))} \quad (3)$$

Then the log-likelihood of trajectories \mathcal{T} is calculated as:

$$L(\mathcal{T}|\theta) = \log \prod_{i=1}^N \prod_{(s,a) \in \xi_i} \pi_\theta(s, a)^{\omega_i} = \sum_{i=1}^N \sum_{(s,a) \in \xi_i} \omega_i \log \pi_\theta(s, a) \quad (4)$$

Herein, ω_i denote the weight for ξ_i , which can be estimated by its frequency of the occurrence. By maximizing the Eq. 4, the parameter θ enables the trajectories \mathcal{T} to have highest probability to be observed given the reward function \mathcal{R}_θ . Once the reward function is learned, the strategy followed by \mathcal{T} can be further induced by any RL method, e.g., policy iteration that we employed in this work.

In general, IRL methods assume the reward function to be unique for all input trajectories. However, it is often the case that the trajectories are heterogeneous and have various reward functions. For example, in ITS, students' decision-making behaviors can have different patterns which cannot be easily captured by a single IRL model. As a result, a model suitable for multiple reward functions is favored.

Algorithm: MLIRL

Input $MDP \setminus R$, trajectories \mathcal{T} , trajectories' weights ω_i , $i = 1, \dots, N$, learning rate α

Initialize reward parameter θ randomly

Repeat

Learn the policy π_θ

Compute $L = \sum_i \sum_{(s,a) \in \xi_i} \omega_i \log(\pi_\theta(s, a))$

Update $\theta = \theta + \alpha \nabla L$

Until target number of iterations completed

3.3 Expectation-maximization IRL

To deal with trajectories with multiple reward functions, i.e., multiple strategies, Babes-Vroman et al. [27] proposed a straight-forward expectation-maximization IRL (EM-IRL). Herein, we adapted the original EM-IRL to automatically determine the optimal number of clusters. Instead of directly assigning the cluster number, we considered a possibly maximal number of clusters, i.e., K_{max} , and a variable k initialized as 2 indicating the current cluster number.

Specifically, to determine the optimal number of clusters, starting from the cluster number $k = 2$, we iteratively implemented the EM procedure, until a pre-defined *stop_criteria* was met. The *stop_criteria* was defined as: either there were some empty clusters generated or the log-likelihood (LL) of the clustering results defined in Eq. 5 varied smaller than a pre-defined threshold comparing to the last iteration, which we set as 10. The LL reflected the clustering performance by measuring the accordance of learned clusters with the correspondingly induced cluster-wise strategies. In Eq. 5, N_j stands for the number of trajectories in cluster j .

$$LL = \sum_{j=1}^k \sum_{i=1}^{N_j} \log(z_{ij}) \quad (5)$$

$$z_{ij} = Pr(\xi_i | \theta_j) = \prod_{(s,a) \in \xi_i} \frac{\pi_{\theta_j}(s, a) \rho_j}{Z}, \quad (6)$$

Before the EM loop, parameters ρ_j and θ_j , $j = 1, \dots, k$, which denoted the estimated prior probability and reward parameter for the j^{th} cluster were randomly initialized.

In the **E step**, the probability that trajectory i belongs to cluster j was calculated by Eq.6, in which Z is a normalization factor; In the **M step**, the prior probability of cluster is updated by Eq. 7. Meanwhile, the reward parameter θ_j can be learned by any IRL and herein we employed the MLIRL with weights of trajectories being z_{ij} .

$$\rho_j = \sum_i \frac{z_{ij}}{N} \quad (7)$$

The E step and M step will be iteratively executed until a target number of iterations is completed, which was set as 80 in this work to ensure the convergence. Finally, we found k clusters when LL got converged, with each cluster standing for a group of trajectories with an unique reward function. Based on these reward functions, we could further induce the cluster-wise strategies.

4. SIMULATION ENVIRONMENTS

Algorithm: EM-IRL

Input $MDP \setminus R$, trajectories \mathcal{T} , maximal number of clusters K_{max}

Initialize $k = 2$

While $k \leq K_{max}$

Initialize ρ_j and θ_j , $j = 1, \dots, k$, randomly

Repeat

E Step: Compute the z_{ij} , $i = 1, \dots, N$

M Step: Update the prior probability ρ_j ; and

Learn reward parameter θ_j via MLIRL

Until target number of iterations completed

If *stop_criteria* is True: **Break**; **Else**: $k = k + 1$

Since the ground-truth of students' subtypes were unknown in advance, it is difficult to directly evaluate the EM-IRL learned clusters from the students' data. Thus, we first carried out EM-IRL in three simulation environments which had decided ground-truth. If different strategies could be accurately distinguished by EM-IRL in simulations, we would be more confident to further deploy it in ITS environment.

4.1 Environment Settings

We explored three simulation environments including Grid World, Highway, and Mountain Car, as shown in Figure 1.

Grid World: adapted from [27], in which three grids were randomly chosen as puddles indicated by bricks in Figure 1(a).

- **States (25)** 5×5 grid-size.
- **Actions (4)** Moving to up, down, left, or right.
- **Strategies (3)** Moving to the 1) upper-right corner; 2) lower-left corner; or 3) lower-right corner.

The rewards are designed for the three strategies: 1) Upper-right corner has the reward of 10; 2) Lower-left corner has the reward of 10; 3) Lower-right corner has the reward of 10. Otherwise, each state was punished -1.

Highway: adapted from a three-lane highway scenario introduced in [50], in which the agent controlled a blue car with three speed levels, which could switch between the three lanes or go off-road on either side. At all timestamps, there would be a red car in one of the three lanes.

- **States (729)** the blue car's speed had 3 levels and could move horizontally in 9 locations; the red car could move vertically in 9 locations and horizontally in 3 locations.
- **Actions (5)** Staying at the current state, speeding up, slowing down, moving left, or moving right.
- **Strategies (2)** 1) Keeping off the left lane (suppose it is under construction); 2) Driving at the fastest speed.

The rewards are designed for the two strategies: 1) Driving on the left lane has the reward of -10; 2) Driving with the lowest level of speed has the reward of -10. In both strategies, off-road is punished -0.5, collision is punished -5, and maintaining the state has no reward.

Mountain Car: adapted from the MountainCar-v0 in OpenAI Gym [51], in which a car was on a one-dimensional track and moves between two mountains.

- **States (80)** 10 horizontal positions with 8 levels of speed.

Figure 1: Three simulation environments: (a) Grid World; (b) Highway; (c) Mountain Car.

Table 1: Cluster-wise and overall purities by EM-IRL clustering in three simulation environments.

Environment	Cluster-wise		Overall Purity (%)
	Strategy Idx	Purity (%)	
Grid World	1	100	100
	2	100	
	3	100	
Highway	1	100	100
	2	100	
Mountain Car	1	100	96.4
	2	93.2	

- **Actions (3)** Pushing left, no pushing, or pushing right.
- **Strategies (2)** 1) Reaching to the right mountain top (the car needs to drive back and forth to build up enough momentum to push up); 2) Parking at the valley bottom.

The rewards are generated for the two strategies: 1) Right mountaintop has the reward of +10; 2) Valley bottom has the reward of +10. Otherwise, each state is punished -1.

In each environment, the initial states were randomly assigned, the transitions between states were stochastic and estimated from the data. For each strategy, we induced a policy via policy iteration and employed it to collect trajectories. Specifically, the number of collected trajectories for each strategy was 500, 1000, and 1000 in three environments, respectively. In each environment, trajectories with various strategies were mixed together and fed into the EM-IRL.

Given the ground-truth of cluster-belongings in simulation environments, the results of EM-IRL were evaluated by the purity of each cluster and across overall clusters. Denote the size of i^{th} cluster as N_i with ground-truth labels \mathbf{L}_i , then the cluster-wise purity is calculated as the number of majority labels divided by the cluster size, i.e., $purity_i = \frac{majority(\mathbf{L}_i)}{N_i}$; and the overall purity is calculated by the mean of purity among all clusters, i.e., $purity = \frac{1}{k} \sum_{i=1}^k purity_i$.

4.2 EM-IRL Results in Three Simulations

The EM-IRL clustering results for the three simulation environments are shown in Table 1, in which the first column is the environment; second and third columns show the index

of strategy and the corresponding cluster-wise purity; the last column show the overall purity among all clusters.

In Grid World, all strategies could be accurately clustered by EM-IRL. Specifically, both cluster-wise purities and overall purity were 100%. Likewise, in Highway, the two strategies were accurately clustered with the purity of 100%. In Mountain Car, a few trajectories of driving to right mountaintop (Strategy 0) were mis-clustered to the parking at valley (Strategy 1). This is because the mis-clustered trajectories tried to move to left to collect enough momentum, which showed very similar behaviors to reaching the valley. Overall, the results suggested the effectiveness of EM-IRL in accurately distinguishing subtypes of trajectories with different strategies in all three simulation environments.

5. ITS LEARNING ENVIRONMENT

Our data was collected by letting students work on a web-based ITS, which taught college students probability, e.g., Addition Theorem and Bayes' Theorem. The instruction was conducted by guiding students go through training problems. For each problem, the tutor provided step-by-step instruction, immediate feedback, and on-demand help. The help was provided via a sequence of increasingly specific hints. The last hint in the sequence, i.e., the bottom-out hint, told the student exactly what to do. During training, the students could make pedagogical decisions on whether to solve the next step by themselves or observe the tutor to solve it. If they choose to solve by themselves, the tutor will *elicit* the solution from them by asking questions; otherwise, the tutor will show or *tell* them the solution directly.

5.1 Data Collection

All students participating in our data collection went through four phases: textbook, pre-test, training, and post-test. During *textbook*, all students studied the domain principles from a probability textbook. They read a general description of each principle, reviewed some examples of it, and solved some single- and multiple-principle problems. Then the students took a *pre-test* which contained 14 problems. During this phase, they would not be given feedback on their answers, nor be allowed to go back to earlier questions (this was also true for the post-test). During the *ITS training* procedure, students received 12 problems in the same order. Each main domain principle was applied at least twice. The minimal number of steps needed to solve each training problem ranged from 20 to 50. Such steps included variable definitions, principle applications, and equation solving. The

number of domain principles required to solve each problem ranged from 3 to 11. Finally, all students took the *post-test* which contained 20 problems in total. 14 of the problems were isomorphic to the problems given in the pre-test phase, while the remaining 6 were harder non-isomorphic multiple-principle problems.

The pre- and post-tests required students to derive an answer by writing and solving one or more equations. We used three scoring rubrics: binary, partial credit, and one-point-per-principle. Under the binary rubric, a solution was worth 1 point if it was completely correct or 0 if not. Under the partial credit rubric, each problem score was defined by the proportion of correct principle applications evident in the solution. A student who correctly applied 4 of 5 possible principles would get a score of 0.8. The one-point-per-principle rubric in turn gave a point for each correct principle application. All of the tests were graded in a double-blind manner by a single experienced grader. The results we presented were based upon the partial-credit rubric but the same results hold for the other two. For comparison purposes, all test scores were normalized to the range of [0, 100].

We measure students' learning performance using normalized learning gain (NLG), which measured their gain *irrespective of their incoming competence*. It is calculated as: $NLG = \frac{post - pre}{100 - pre}$, where *pre* and *post* refer to the students' test scores before and after the ITS training respectively and 100 is the maximum score. Herein, for the post-test, we considered all 20 problems that are either isomorphic and non-isomorphic. In addition, an isomorphic NLG (Iso_NLG) was also measured. Unlike NLG, the Iso_NLG was calculated based on the pre- and isomorphic post-test scores, which contained only 14 isomorphic multiple-principle problems.

5.2 States & Actions

Our dataset contains 127 students. Each student spent ~ 2 hours on the system and completed around 400 steps.

States 142 state features were extracted from the student-system interaction log data. Specifically, the features can be grouped into five categories:

- **Autonomy** (10 features): the amount of work done by a student, such as the number of elicits since the last tell;
- **Temporal** (29): time related information about the student's behavior, such as the average time per step;
- **Problem Solving** (35): information about the current problem solving context, such as problem difficulty;
- **Performance** (57): information about the student's performance so far, such as the percentage of correct entries;
- **Hints** (11): information about the student's hint usage, such as the total number of hints requested.

For each category, we employed K-means clustering to get the discretized states. By selecting an elbow of errors when the clustering results got converged, the number of states for each category of features was determined as follows: Autonomy (3 states), Temporal (4), Problem Solving (3), Performance (4), and Hints (3). As a result, we got 432 discrete states totally. Based on the discretized states, we estimated the transition probabilities from all available data.

Actions The students can take two action of elicit/tell, i.e., to *elicit* the solution by themselves through asking questions, or to let the tutor *tell* them the solution directly.

6. EXPERIMENTAL SETTINGS

6.1 Student Subtyping by EM-IRL

Based on the EM-IRL learned clusters, we conducted analyses by checking the statistical significance among different clusters' learning performance, including the pre-test scores, isomorphic NLG (Iso_NLG), NLG, students' learning time on the training task (Time), and the percentage of elicit in students' decisions (Elicit_Perc).

6.2 Student Subtyping by Other Methods

6.2.1 Clustering by Traditional Methods

To evaluate the clustering performance of EM-IRL, we compared it with three other clustering methods: two K-means based approaches that took the pre-test scores and the learning state in the final step as the input respectively and a K-medoids based approach that took dynamic time warping (DTW) [52] distance between trajectories as the input. The K-means based approaches were static-information-based clustering while the K-medoids based DTW considered dynamic state transitions in the trajectories. In our experiments, each of these methods generated three clusters and for each cluster, the MLIRL was employed to learn a strategy. Based on the learned strategies, we calculated the log-likelihood (LL, referring to Eq. 5) of observing such clustering results.

6.2.2 Clustering by Matching RL / IRL Policies

We further explored whether RL or IRL policies could model the heterogeneity in student decision-makings. The inducing of these two policies are detailed as follows.

Inducing the RL policy: To investigate whether students' learning strategies could be distinguished from the tutor's perspective, we compared students' decisions to a RL induced pedagogical policy and clustered the students based on the matching rate. Since the RL policy was induced with the goal of improving students' learning performance, it is expected that the group with a higher matching rate with the RL policy would have better learning performance.

Specifically, we applied RL to learn a pedagogical policy that determines whether the next step should be elicit or tell (the same decisions students made in our ITS). The training data set contained 1,118 students' interaction logs collected from a series of seven prior studies which followed the identical procedure and learning materials as the students in this study described in Section 5. The same 142 features used by EM-IRL were extracted from the logs and used to induce the policy. In an empirical classroom study, the policy was compared with a deep Q-network (DQN) induced policy and a random policy. Results showed that the RL policy significantly outperformed both of them [21].

Once the RL policy was induced, we applied it on the student decision-making data (127 students) to see what decision the RL policy would make on each step. Then, we calculated the matching rate between students' decisions and the RL policy individually for each student. Based on the matching

rates, the students were split into three groups via K-means clustering, denoted as High, Medium, or Low based on the average matching rate of the group.

Inducing the IRL Policy: Similarly, to investigate whether students' learning strategies could be distinguished from their own perspective, we applied IRL to induce a policy from student decision-making data and compared students' decisions with the IRL policy. Given that our data analysis showed that most of students learned significantly from ITS training, herein, we assumed that a majority of students completed the training with the goal to learn. Thus, we expected that the group with a higher matching rate with the the IRL policy would have better learning performance.

The IRL policy was induced from the 127 students who were given the opportunities to make pedagogical decision during training. Herein, the MLIRL algorithm [27] was utilized for policy induction. Similar to the RL based method, the IRL policy was applied back to students' data to calculate the matching rate between students' decisions and the IRL policy. Then, K-means clustering was applied on the matching rate to cluster students into High, Medium, or Low groups.

7. RESULTS

7.1 Student Subtyping by EM-IRL

Fitting students' data to the EM-IRL framework in Section 3.3, when *stop_criteria* was met, we got three clusters. Table 2 shows the EM-IRL subtyping results. From left to right, it shows the students' subtypes, number of students (# Stu), pre-test score (Pre), isomorphic NLG (Iso_NLG), NLG, time on the training task (Time), and percentage of elicit in students' decisions (Elicit_Perc). Based on statistical analysis, we named the three resulting clusters as: *learning-oriented*, *efficient-oriented*, and *no learning*.

A one-way ANOVA analysis on pre-test scores showed no significant difference among the three clusters: $F(2, 124) = 1.36$, $p = 0.260$, $\eta = 0.022$. This suggested that students in the three clusters were balanced in incoming competence. To measure students' learning gain in training, we conducted analyses on their Iso_NLG and NLG. A one-way ANOVA analysis on Iso_NLG showed a significant difference among the three clusters: $F(2, 124) = 3.24$, $p = 0.042$, $\eta = 0.050$. Subsequent contrast analysis revealed that *learning-oriented* > *no learning*: $t(124) = 2.54$, $p = 0.012$, $d = 0.75$ and *efficient-oriented* > *no learning*: $t(124) = 2.19$, $p = 0.030$, $d = 0.54$. Similar results were found for NLG in that a one-way ANOVA analysis showed a significant difference among the three clusters: $F(2, 124) = 3.73$, $p = 0.027$, $\eta = 0.057$. Subsequent contrast analysis revealed that *learning-oriented* and *efficient-oriented* significantly outperformed *no learning*: $t(124) = 2.73$, $p = 0.007$, $d = 0.77$ and $t(124) = 2.15$, $p = 0.033$, $d = 0.52$ respectively.

In terms of time on task, a one-way ANOVA analysis showed a significant difference among the three clusters: $F(2, 124) = 5.81$, $p = 0.004$, $\eta = 0.086$. Subsequent contrast analysis indicated that *learning-oriented* took longer time on task than the other two clusters: $t(124) = -3.11$, $p = 0.002$, $d = 0.58$ for *efficient-oriented* and $t(124) = 2.37$, $p = 0.019$, $d = 0.63$ for *no learning*. A contrast analysis on the percentage of elicit in students' decisions revealed that *learning-*

oriented took significantly more elicit actions than *no learning*: $t(124) = 2.24$, $p = 0.027$, $d = 0.70$.

To summarize, the *learning-oriented* subtype spent significantly more time than the other two groups on the training task and achieved the best performance on both Iso_NLG and NLG (significantly higher than *no learning*). This suggested that learning-oriented students mainly focused on learning the materials, regardless of the time they may spend. The *efficient-oriented* subtype significantly outperformed *no learning* on learning performance and at the same time spent significantly less time than *learning-oriented*. This suggested that *efficient-oriented* students could balance learning gain and time on task. Finally, the *no learning* subtype achieved the lowest learning outcomes.

7.2 Student Subtyping by Other Methods

7.2.1 Clustering by Traditional Methods

We compared our EM-IRL with three traditional baseline clustering methods, namely K-means on the pre-test score (K-means on Pre); K-means on the learning state (142 features) in the final step (K-means on Final Step); K-medoids on the DTW distance among trajectories [52], which is calculated based on the 142 features (K-medoids on DTW). The results are shown in Table 3, with the two columns being clustering method and the resulting log-likelihood (LL).

Overall, results showed that the dynamic-information-based clustering approaches (K-medoids on DTW and EM-IRL) performed better than static-information-based approaches (K-means on Pre and K-means on Final Step). Between the two static-information-based approaches, K-means on final Step performed better than K-means on pre-test. This is not surprising because the state in the final step included information generated during training while the pre-test score only included information till the end of pre-test. Between the two dynamic-information-based approaches, EM-IRL outperformed K-medoids on DTW. A possible reason is that EM-IRL took both states and actions into account while K-medoids on DTW considered only the states in trajectories.

7.2.2 Clustering by Matching RL / IRL Policies

Results of Matching with the RL Policy: Based on the matching rate with the RL policy, we got three clusters by K-means: High ($M = .84$, $SD = .05$), Medium ($M = .70$, $SD = .05$), and Low ($M = .52$, $SD = .07$). A one-way ANOVA analysis over the matching rate showed a significant difference: $F(2, 124) = 339.87$, $p < 0.0001$, $\eta = 0.846$. Subsequent contrast analysis showed that: High > Medium: $t(124) = 4.38$, $p < 0.0001$, $d = 0.99$ and Medium > Low: $t(124) = 8.01$, $p < 0.0001$, $d = 1.70$.

A one-way ANOVA analysis on pre-test showed there was no significant difference among the three groups: $F(2, 124) = 0.26$, $p = 0.771$, $\eta = 0.004$. Analyses on Iso_NLG (calculated based on pre-test and isomorphic post-test) and NLG (calculated based on pre-test and full post-test, which contains six additional hard problems) also showed no significant difference among the three groups. In terms of time on the training task, there was a significant difference among the three groups: High ($M = 2.40$, $SD = .50$), Medium ($M = 2.42$, $SD = .66$), and Low ($M = 1.88$, $SD = .40$).

Table 2: EM-IRL clustering results in ITS environment.

Subtype	#Stu	Pre	Iso_NLG	NLG	Time	Elicit_Perc (%)
learning-oriented	50	73.9(16.8)	55.9(45.3)	23.4(53.6)	2.52(.70)	87.53(13.40)
efficient-oriented	64	76.2(14.5)	43.9(92.4)	-4.4(127.2)	2.18(.45)	84.93(15.02)
no learning	13	81.9(17.4)	-21.1(212.1)	-98.4(340.4)	2.10(.50)	77.06(20.04)

Table 3: Comparison of the log-likelihood (LL) for different clustering methods

Method	LL ($\times 10^3$)
K-means on Pre	-10.68
K-means on Final Step	-9.60
K-medoids on DTW	-8.83
EM-IRL	-6.36

A one-way AVONA on time shows: $F(2, 124) = 9.21$, $p = 0.0002$, $\eta = 0.129$. Subsequent contrast analysis revealed that the High and Medium groups spent significantly more time than the Low group: $t(124) = 3.85$, $p = 0.0002$, $d = 1.11$ and $t(124) = 3.99$, $p = 0.0001$, $d = 0.92$, respectively. An analysis on the percentage of elicit in students' decisions showed a significant difference among the three groups: $F(2, 124) = 66.97$, $p < 0.0001$, $\eta = 0.519$. Subsequent contrast analysis revealed that High > Medium: $t(124) = 4.38$, $p < 0.0001$, $d = 0.99$ and Medium > Low: $t(124) = 8.01$, $p < 0.0001$, $d = 1.70$.

The results showed that by matching with the RL strategy, we could differentiate students' time-consuming strategies from time-efficient strategies. However, it was not able to identify the student subtypes that made a difference in the learning performance. This suggested the presence of a gap between tutor's and students' strategies. Specifically, comparing to taking actions following the tutor's decisions passively, the students might prefer actively direct their own learning process. Therefore, when deploying the tutor's strategy to students, it might not promote the learning performance as expected.

Results of Matching with the IRL Policy: Based on the matching rate with the IRL policy, we got three clusters by K-means: High ($M = .86$, $SD = .05$), Medium ($M = .71$, $SD = .05$), and Low ($M = .54$, $SD = .06$). A one-way ANOVA analysis over the matching rate showed a significant difference among the three groups: $F(2, 124) = 360.99$, $p < 0.0001$, $\eta = 0.853$. Subsequent contrast analysis showed that: High > Medium: $t(124) = 15.92$, $p < 0.0001$, $d = 3.37$ and Medium > Low: $t(124) = 13.52$, $p < 0.0001$, $d = 3.23$.

A one-way ANOVA analysis on pre-test showed there was no significant difference among the three groups: $F(2, 124) = 1.17$, $p = 0.314$, $\eta = 0.019$. Analyses on the Iso_NLG and NLG also showed no significant difference among the three groups. In terms of time on the training task, there was a significant difference among the three groups: High ($M = 2.44$, $SD = .54$), Medium ($M = 2.27$, $SD = .68$), and Low ($M = 2.08$, $SD = .42$). A one-way AVONA on time shows: $F(2, 124) = 3.11$, $p = 0.048$, $\eta = 0.048$. Sub-

sequent contrast analysis showed that the High group spent significantly more time than the Low group: $t(124) = 2.43$, $p = 0.017$, $d = 0.70$. An analysis on the percentage of elicit in students' decisions showed a significant difference among the three groups: $F(2, 124) = 93.92$, $p < 0.0001$, $\eta = 0.602$. Subsequent contrast analysis revealed that High > Medium: $t(124) = 7.95$, $p < 0.0001$, $d = 1.83$ and Medium > Low: $t(124) = 7.08$, $p < 0.0001$, $d = 1.43$.

The results showed that IRL based policy matching was able to cluster the students' strategies different in time. However, it was unable to learn specific subtype of students whose strategy will lead to better learning outcomes. One possible reason that the IRL-based analyses could not identify the learning-performance-impactful strategies is that a single policy was insufficient to effectively generalize the decision-making patterns for the overall students. Different students might follow heterogeneous decision-making strategies.

In summary, the results suggested that EM-IRL could effectively conduct student subtyping reflecting different decision-making strategies. As a contrast, clustering by traditional methods or by matching RL/IRL policies could not find desired student subtypes.

8. CONCLUSIONS

In this paper, we investigated students' subtyping via EM-IRL. By analyzing students' subtyping, we aimed at putting ourselves in the shoes of students to better understand their decision-making. To evaluate the performance of EM-IRL, we first applied it to three simulation environments, where the EM-IRL displayed robust performance to accurately cluster the trajectories with different strategies. Given the accurate clustering results in simulators, we were more confident to further apply EM-IRL to real world longitudinal students' logs collected from an ITS. The results suggested that the EM-IRL could effectively group students with different subtypes, e.g., learning-oriented, efficient-oriented, and no-learning. As a contrast, clustering by traditional methods or by matching RL/IRL policies could not find desired subtypes. The subtyping results showed the potential of providing tutors evidence to give more customized interventions to better assist students' learning. In the future, we will conduct early clustering to detect students' strategies as early as possible. Besides, empirical studies will be carried out to evaluate the effectiveness of subtyping-based interventions to improve the targeted group of students.

ABSTRACT

Student procrastination, as the voluntary delay of intended work despite expecting to be worse off for the delay, is an important factor with potentially negative consequences in student well-being and learning. In online educational settings such as Massive Open Online Courses (MOOCs), the effect of procrastination is considered to be even more prevalent and detrimental, as online courses are often self-paced and self-directed, where higher levels of self-regulated learning are expected from the students. Past research has mainly described students' procrastination by either static time-related measures (e.g. averaged starting time over all assignments per student), or by temporal models' parameters, under the assumptions that student activities take place at a constant rate (e.g. Homogeneous Poisson models), and that student interactions with one learning material are independent of interactions with another. In this work, we propose to consider the interdependence between the students' temporal activities while modeling their sequences in a continuous time scale. To this end, we propose to model the interaction sequence between each student and each course module, i.e. each module-student pair, as Multi-dimensional Hawkes processes, which not only capture the relationship between students' learning activities and their exogenous stimuli such as assignment deadlines, but also capture the endogenous responses *within* and *between* types of learning materials. Our experiments show that not only there exists dependencies between students' historical activities and the future ones when different types of learning materials are involved, such dependencies also provide meaningful interpretations in terms of students' procrastination behaviors. Furthermore, our findings show that in addition to association with delay, the parameters learned by multi-dimensional Hawkes processes provide more procrastination-related information and can improve our explanation of student grades.

1. INTRODUCTION

Student academic procrastination has shown to have negative effects on students' learning and well-being. Procrastination is prevalent in different academic settings like traditional classrooms, and could be even more widespread in online learning environments, as higher levels of time-management and self-regulated learning (SRL) skills are required [47, 3, 16]. To describe and measure student procrastination, past research has been mainly relying on either self-reported surveys (e.g. [27]) or time-related features that are associated with students' dilatory behaviors (e.g. [10]). As procrastination is inherently subjective, self-reported surveys have been heavily used in earlier research, to differentiate procrastinators and non-procrastinators by emphasizing on measuring the perceptions of the students. Although self-report survey measures capture students' retrospective reports of their studying and delaying behaviors, they are administered in a cross-sectional manner, rely on students' memory, and are usually static point estimates that summarize students' *average* degree of procrastination.

Considering the noises of self-reported data [37], in more recent studies, more focus has been given to the behavioral side of the procrastination, where time-related measures were proposed and used as the representation of students' procrastination. For example, measures such as students' average delays in starting coursework, the average time they spent in doing assignments, students' average paces of viewing lectures have been studied as factors of procrastination [2, 10, 15, 6, 22]. However, these measures lack the ability to describe students' continuous behaviors within a period of time. An analogy to such methods is to describe the entire distribution using the sample mean, without fully knowing the distribution. To tackle this limitation, more recently, emphasis has been on modeling the time points of student activities that are extracted from students' learning trajectory data (e.g. log or click-streams of student historical actions), via stochastic models. For example in [33], Park et al. modeled students' per-day activity counts during each week of the course via a Poisson mixture model, which models the entire trajectory of each student activities during a weekly module. Other factors that have been considered to be important in describing procrastination in the past research are the effects of different learning materials (e.g. forums and quizzes) as well as students' interactions with them (e.g. [1, 28]). However, to the best of our knowledge, no past work has considered the possible time dependencies within and between students' interactions with dif-

ferent learning material types. For example, viewing video lectures more intensively *mostly before* the first attempt of an assignment may suggest that a student prefer to learn the materials first before trying the assignment. On the other hand, watching lecture videos *dominantly after* the first attempt of an assignment may suggest that the student prefer to try the assignment first and then go through the video lectures if they encountered any problems.

To summarize, past research has attempted to describe procrastination using static time measures, or measures summarized from more sophisticated temporal models, based on students' interactions with one or more learning materials. However, two important factors of student behaviors and their association with procrastination have not been fully explored: (1) the dependencies between students' past and future interactions within each learning material type (e.g. knowing a student has looked at lecture slides at some time, how and when are they going to have the next activity?) and (2) the dependencies between students' interactions with different types of learning materials (e.g. are watching video lecture usually followed by a submission of an assignment?) In this work, we aim to address these two factors by answering the following questions: within each learning module, that is the unit of a course that learning materials are provided, (Q1) are the past activities independent of future ones? Or some activities can trigger other ones to arrive within a short period of time (i.e. time dependencies between activities)? And (Q2), are students' interactions with one type of learning material (e.g., video lectures) independent from another type (e.g., discussion forums)? Furthermore, (Q3) if such dependencies exist, how are they associated with student procrastination? (i.e. the dependencies between a student's past and future activities as well as dependencies a student's interactions with one learning material with another.)

As a result, our goal is to find the missing link between students' procrastination and students' activities within and between different types of online learning materials. To achieve this goal, we propose to use multi dimensional Hawkes processes as a powerful tool that addresses the above mentioned concerns in student procrastination analysis. Particularly, we represent all activities on one type of learning material as one dimension in the multi-dimensional Hawkes model. We show that this model better fits our data, in comparison to baseline temporal processes. Also, to answer Q1 and Q2, we demonstrate that it can capture both students' reactions to the deadlines as action-triggering factors that come externally (i.e. exogenous stimuli), and students' responses to the previous interactions with different types of learning materials, such as video lectures, assignments, and discussions (i.e. self-excitement). By doing so, we can understand students' procrastination behavior from a stochastic process point of view, with two main stimuli: (1) some of the students' activities can be viewed as a response to an external stimulus, e.g. deadlines of the assignments (2) some other student activities can be viewed as the results of previous interactions that the student had with the same or other learning material types. Based on the model parameters, to answer Q3, we also propose a measure that not only describes student procrastination but also is able to explain student performance better than the static delay measure.

The outline of this paper can be summarized as follows: In Section 2, we go over three main bodies of the related work; in Section 4 we go over the details of the dataset that we use; in Section 4, we provide the intuition of using the Hawkes model, then statistically and visually show that a Hawkes process is a proper choice for modeling module-student interactions; in Section 5, we formally define our problem and introduce the multi-dimensional Hawkes model that we use in this study. We perform various experiments in section 6, to analyze the model parameters, explain their interpretation, and associate them with procrastination as well as students' assignment grades. Finally, the conclusion of this work is summarized in Section 7.

2. RELATED WORK

Students' procrastination In the past research on student procrastination, the main focus has been on the measures that capture either students' perceptions (e.g. self-reported surveys on procrastination [35, 41, 40, 12, 23]), or static measures that describe students' dilatory behaviors as the representation of procrastination [15, 11, 44, 33]. For example, in [10], Cerezo et al. studied 140 undergraduate and used measures such as students' delay and time-spent variables to describe procrastination. For another example, in [2], Asarta and Schmidt studied students' behaviors in accessing lecture notes of a blended-learning course, and proposed to use features such as pacing, anti-cramming, and consistency in reviewing course materials. A few recent works have tried to model student activities to provide a temporal perspective of procrastination behavior. For example, Backhage et al. proposed a model that captures procrastination-deadline cycles of all students in the course using a stochastic temporal model [4]. However, this model assumes that all students follow the same procrastination behavior during the course and does not distinguish the differences between student behaviors. In [33], Park et al. assumed that students' daily activity counts follow a mixture Poisson distribution, which is a mixture of a procrastination component and a non-procrastination component. Particularly, by assuming the independence between students' past and future activities, they proposed to model each day of the week by a Poisson with a constant rate for all weeks. In the end, they described procrastinators as the ones with a dominant procrastination component versus the non-procrastination one, i.e. the students who have a fast-increasing activity counts towards the end of the week. Moon et al. assumed that procrastination behavior over time can be described by a curvilinear growth curve and modeled it using latent growth curve modeling. To validate this assumption, they compared the curvilinear model with a non-growth and a linear model and showed that their model has a better goodness-of-fit than the baseline models [30]. In contrast with the existing research that either uses summary variables or ignores the dependence between different student activities, in this paper we aim to model the temporal activity interrelationships and associate them with student procrastination.

Modeling students' engagement using their learning trajectories. Other relevant studies to our work are the ones that model student learning trajectories to understand other aspects of their behaviors, such as student engagement in online learning environments. While many past

studies focused mostly on utilizing cumulative factors such as frequency of watching videos or using discussion forums [39, 17, 34, 13], more recent work attempted to build more complex models of student behaviors. For example, in [46], Zhu et al. constructed students' social connection networks based on students' weekly post-reply dynamics, along with node attributes, such as assignment scores. Particularly, they used an exponential random graph model to compute the structural features of the social connection networks, to understand the relationship between students' engagement in the forums and their performances in the assignments. In another example, Lan et al. proposed a statistical model, which consists of two components: a learning model and a response model [25]. These two models represent nine behavioral features extracted from students' video-watching clickstreams and in-video quiz responses in one MOOC course, with the aim to find the behavioral features that lead to high levels of student engagement. Similarly, Kizilcec et al. classified students' behaviors based on binary features extracted from students' log data (1 if a student had any activities that are associated with a learning material, 0 otherwise, for all learning materials) [24]. As a result, they identified 4 behavioral types: completing, auditing, disengaging, and sampling, from these binary features. For another similar example, Gelman et al. extracted student features from students' log data as well and applied Nonnegative Matrix Factorization to find 5 types of student behaviors - deep, consistent, bursty, introduction, and sampling [18]. Particularly, the authors used a procrastination indicator as a feature, that is, the average amount of time left before the deadline when a student submits their assignments. In summary, past research on modeling student engagement is similar to our study in the sense that the models utilize students' activities that were extracted from students' log data. However, it differs to ours in the following two ways: (1) the models usually define students' engagement levels based on the *counts* of students' historical activities, without directly modeling students' learning trajectories as stochastic processes, (2) the aim is usually to model or predict students' future engagement levels, rather than studying students' procrastination and its association with students' performance.

Hawkes in education. Hawkes processes, a family of stochastic point processes, have been frequently used to model complicated time-stamped events in continuous time. Due to Hawkes process's capability to model scenarios where historical events influence future activities, it has been frequently used in finance [5] and seismology [32] and has been gradually becoming a useful modeling tool in the domain of social media [7, 36, 29], as well as recommendation systems [14, 43, 21, 38]. In the education domain, a few works have used Hawkes processes so far, especially to model social and interaction data among students [19, 20, 26]. For example, Lan et al. proposed a single-dimensional Hawkes model to recommend relevant discussion threads to students according to their historical interactions with course forums. In a similar application, a Hawkes model is suggested by Von Davier et al. to model the collaboration dynamics between students within and between groups [42]. Along this line, Halpin et al. used multi-dimensional Hawkes processes to understand students' collaboration with each other [19, 20]. Another interesting application of the Hawkes process in the

education domain is the work by Boerner et al. that analyzed the association between student skills and the skills required by professional jobs [8]. In another recent work, Cai et al. used Hawkes processes as a step in their model to predict which video a student will watch next based on their historical interactions with the videos in an edX course [9]. They use long and short multi-dimensional Hawkes processes that differentiates the long-term and short-term temporal dependencies between video-watching actions. None of the above works uses the Hawkes processes to model the procrastination behavior, nor considers course deadlines and milestones in their application of the Hawkes process.

3. DATASET

Our dataset is publicly collected from the Canvas Network¹ MOOC platform [31], which is an online platform that hosts various open online courses in different academic disciplines, such as Computer science, Social Science, and Business management. These courses have multiple types of learning resources, including Wiki pages, assignments (or quizzes), and discussions. Assignments can be quiz-style or in a longer format where students need to upload a file to complete the submission. Each learning module is associated with one Wiki page. In total, CANVAS data contains 389 anonymized courses where the names of students and courses along with the contents of discussions and assignment (or quiz) submissions are not available.

In this work, we mainly focus on exploring the student learning trace data. Specifically, we select a computer science course (course id: 770000832960058) that best fits the following criteria: (1) having a large number of students²; (2) including multiple types of learning materials (such as video lectures, assignments, discussions); and (3) containing a large number of student historical learning activities. To obtain student learning activity data, we use Canvas logs files (Pageview requests). We divide the learning activities into three types. Specifically, we consider viewing the lectures, downloading the attached files, and previewing the attached files as the activities associated with video lectures (*L*). Activities that include viewing, creating, saving, updating, and submitting each assignment attempt are associated with assignments (*A*). Finally, we consider reading (marking as read), subscribing, creating, replying, and editing discussion entries, discussion topics, and direct messages as discussion-related activities (*D*).

We separate the data in module-student pairs, as we aim to model each student's interactions with each individual learning module. As each module has its specific deadlines according to the course design, we choose each module rather than the whole course as the unit of our study. Also, different modules usually have different learning objectives, which will possibly trigger different behaviors. By doing so, we are able to capture a finer granularity of the data. Finally, we have 731 students and $\sim 946K$ learning activities in the selected course.

¹<http://canvas.net>

²Enrolled students who have missed more than 50% of the assignment submissions during the courses, along with those who did not receive a final grade, are considered as dropouts and are disregarded in this study.

4. BACKGROUND: HAWKES PROCESS AS A FIT TO STUDENT ACTIVITIES

Since we want to study the interactions between students and modules from a temporal aspect, point processes are one of the best choices for our application. Additionally, because of the interaction irregularities in our application, we must select a point process that can handle this type of information. Specifically, past studies have shown that students' activities can take place in an irregular manner during various periods of a course, particularly affected by milestones such as assignment deadlines and exam dates [16]. As a result, the point processes that follow a constant rate, such as Poisson processes, are not the appropriate model for our application. In Poisson processes, the main assumption is the independence between past and future occurrences of the events, which can not be met in student studying behaviors. Not only some student activities happen in response to the course milestones, but also a part of these activities can be interrelated with each other. For example, a student whose goal is to start discussing a topic in the discussion forum may watch a video lecture about the same topic before posting in the forum. To meet the temporality and interdependence assumptions of our application, we choose to model student activities during course modules with Hawkes processes.

One of the most important properties of the Hawkes process is its ability to deal with the interrelationships between future and past activities. This is in contrast with the memoryless Poisson process where all activities are assumed to be independent of each other. More importantly, the Hawkes process allows the activities to be excited both exogenously (by external stimuli, similar to the Poisson process) and endogenously (self-excitement, by internal stimuli). In other words, the Hawkes process has a branching process point of view. It assumes that some activities arrive as a result of exogenous stimuli (i.e. immigrant activities). Then, the immigrant activities can trigger their following activities (i.e. offspring activities), and those offspring activities can further trigger their own offspring activities, and so on. That is, the offsprings of an immigrant activity are structured into a latent cluster because they are all triggered by the same immigrant and arrive more closely to each other than the activities that are in other clusters.

As a result, the Hawkes process can capture more information than the Poisson process or other point processes that use the average base rate as the only model parameter. This can be very helpful when modeling processes that have the same number of activities, but with different activity occurrence distributions. To demonstrate this ability in Hawkes processes, we show the event occurrence patterns of two simulated Hawkes processes with the same number of activities, but different parameters in Figure 1. We can see that process 1 has more bursty but less regular occurrences compared to process 2, in which less burstiness but a higher regularity is observed. Since both simulated Hawkes processes have the same number of activities in the history, a Poisson model is not able to capture such differences because the base rates of the two processes would be the same in a Poisson process.

For an educational application, there is a natural mapping between student activity events and Hawkes processes. The smaller student activity chunks toward a goal or deadline can

Figure 1: An illustration of two different processes that have the same number of occurrences. The x-axis is the time and the y-axis is the intensity of event occurrences per time unit. Both processes have 29 occurrences but with very different characteristics that will be ignored by Poisson processes.

be examples of an immigrant's offsprings: students break down the big tasks (the whole process) into small sub-tasks (latent clusters). The deadline (external stimuli) of a big task, such as an assignment deadline, can trigger subsequent activities that are associated with the small tasks. These activities arrive closely one after another in a so-called bursty manner (self-excitement)³. We demonstrate that Hawkes processes are a good fit to our application by showcasing two examples. First, we show that the module-student pair interactions can not be properly modeled by processes that only model an average base rate, such as Poisson processes. To do this, we conduct a goodness of fit test on the inter-arrival times of module-student pairs in our dataset against the inter-arrival time distribution of a Poisson process, which is $\exp(1)$. We use the Kolmogorov-Smirnov test to evaluate the fit's significance. The mean p -value of this test among all module-student pairs in our dataset is $2.77E-6$ with a standard deviation of $6.41E-5$, which shows that module-student pairs do not fit Poisson processes.

Second, we empirically demonstrate the burstiness of module-student interactions. To do this, we show that the Poissonian property of only having a constant base rate is not present in the observed activities of a sample module-student pair from our dataset. Specifically, we use the 1-lag autocorrelation of activity inter-arrival times to conduct our test. The inter-arrival time is defined as the difference between the arrival times of two consecutive activity occurrences. We first simulate a Poisson process with the base rate equal to the average number of activities in our sample activity sequence. Then, we compare the 1-lag autocorrelation in this simulated sequence with the autocorrelation of our sample sequence. Since all inter-arrival times in Poisson processes follow $\exp(1)$, we expect the autocorrelation of the simulated Poisson process to be 0 (no correlation). In contrast, we expect to see a non-zero autocorrelation in

³It is worth noting that in regular applications of Hawkes processes an activity at time t can trigger later activities at times $\tau > t$. However, in our application, student activities are triggered by the upcoming deadlines in the future. Similarly, earlier chunks of studying sub-tasks at times $\tau < t$ can be offsprings of future studying tasks at time t towards a deadline. As a result, to make the Hawkes process applicable to our problem, we use a reversed activity timeline for our data. This does not affect our model, optimization, or learned parameters.

a bursty self-exciting sequence. Figure. 2 shows the scatter plot of activity inter-arrival times in the original sequence vs. the sequence with lag 1 for each of the two sequences. As we can see, little autocorrelation is spotted in the Poisson process, whereas the pattern of autocorrelation in real data is shown to be not random. Specifically, we can see that most of the lag-1 vs. original inter-arrival times for the sample sequence are scattered around the axes, meaning that dense activities are often followed by long pauses, and vice versa.

Figure 2: A demonstration of burstiness presented in the interactions of a sample module-student pair: 1-lag autocorrelation scatter plots shows that long pauses are often observed after dense and bursty activities.

It is worth mentioning that our goal is not to directly compare to Poisson models. Rather, we are demonstrating here that we must model the data in a way that captures long-term temporal properties of the processes and their irregularities, rather than static measures such as the count or average number of activities that only provide one facet of the whole picture.

5. METHOD: MULTI-DIMENSIONAL HAWKES PROCESSES TO MODEL ACTIVITY-TYPE RELATIONS

In this section, we introduce the method we use in this study to model student behaviors. More specifically, we illustrate multi-dimensional Hawkes processes and how we apply them to our application. The previous section illustrated how Hawkes process is a good fit for student activities as future activities in module-student pairs could be related to the past activities. In those illustrations, all activities in a module-student pair are considered to be homogeneous or of one single type. In other words, the self-exciting property of the interactions between students and module are assumed to be uniform throughout different kinds of activities, whether it is watching a video lecture, participating in a discussion, or attempting to submit a solution to an assignment. However, in reality, students might exhibit different learning behaviors or use different learning strategies towards different types of learning materials. For example, some students may have more intense and frequent activities when viewing module lectures but less frequent pace when it comes to the discussions. Furthermore, when a student is interacting with two different types of learning materials, different time dependencies may exist between student's in-

Figure 3: Hawkes processes in module-lecture dimension L , module-assignment dimension A , and module-discussion D , and their mutual excitation. A vertical bar is the representation of an activity occurrence and a red arrow shows the influence of one activity (head) on another (end).

teractions with the two. For example, a student may often visit discussion forums very closely after viewing lecture slides, i.e. strong time dependency between lectures and discussions (more specifically, discussion after lectures), but such dependencies may be less obvious for another student.

To address this challenge, we model the students' activities on one type of learning material as an individual Hawkes process, and model all such processes simultaneously as multi-dimensional Hawkes Processes. In particular, in the rest of this study, we refer the collection of activities that associate with one type of learning material as a Hawkes process *dimension*. A multi-dimensional Hawkes model not only allows dependency between past and future activities within each dimension (i.e. self-excitation) to be modeled, it is also able to capture the possible dependencies between different types of activities (i.e. excitation between dimensions). For example, scenarios such as submitting the first attempt of an assignment and then starting the second attempt (self-excitation), or, posting a question in the discussion forum after watching a video lecture (excitation between dimensions) can be well described by multi-dimensional Hawkes processes.

In this study, based on the learning material types presented in our dataset, we consider 3 dimensions to analyze students' learning behaviors, namely video lecture dimension L , assignments dimension A and discussions dimension D . To illustrate how multi-dimensional Hawkes processes work in modeling between-dimension excitation, in Figure 3, we show 3 sample Hawkes processes that respectively comes from dimensions L , A , and D . Within each dimension, we use vertical dashed lines to represent the occurrences of activities that take place in that dimension⁴. Activities in one dimension can trigger other activities in another dimensions. This constitutes the influence between different dimensions. We indicate the between-dimension triggers by the red arrows that point from the parent activity to the offspring. For example, the third activity in dimension D in this figure triggers the fifth activity in dimension A as well as the sixth activity in dimension L .

We now formally explain the multi-dimensional Hawkes model and how it can be interpreted according to our application. Suppose that for each module-student pair (m, u) , we are

⁴The height of each bar does not represent intensity and does not have any particular meaning in this figure

given a sequence of arrival times for N_{mu} number of activities that are associated with module m and student u . We represent the sequence of each module student pair as in $(m, u) = \{\tau_i\}_{i=1}^{N_{mu}}$, where $\tau_i = (t_i, d_i)$ corresponds to the arrival time of i^{th} activity and the dimension (activity type) d_i to which activity i belongs. For example, suppose student u has 3 total activities in module m . If u submitted an assignment at time 1, then checked a lecture's slides at time 5, and had some discussion posted at time 8, then $(m, u) = \{(t_1 = 1, d_1 = A), (t_2 = 5, d_2 = L), (t_3 = 8, d_3 = D)\}$, with A , L and D representing assignments, video lectures, and discussions respectively. For each dimension $d \in [L, A, D]$ and each module-student pair (m, u) , we further use the sequence $T_d(\tau_i) = \{t_i \in \tau_i | \tau_i \in (m, u), d_i = d\}$, to represent the type d learning activities that student u performs in module m as a process. According to the multi-dimensional Hawkes model, we can explain the intensity of $T_d(\tau_j)$ according to the following function:

$$\lambda_d(t) = \mu_d + \sum_{d', t_j < t} \phi_{dd'}(t - t_j), \quad (1)$$

where μ_d describes the average number of activities occurred per unit time that are triggered by exogenous stimuli (the process's base rate in dimension d); and ϕ (the kernel function) represents the function that explains the endogenous stimuli, or the triggering effects from the previous ($t_j < t$) activities in the same dimension or another dimension (d'). In other words, $\phi_{dd'}$ controls the total influence that dimension d exerts on dimension d' , as a function of activity inter-arrival times ($t - t_j$). Using an exponential kernel function for ϕ , the multi-dimensional Hawkes model can be rewritten as in Equation 2.

$$\lambda_d(t) = \mu_d + \sum_{d'} \alpha_{dd'} \sum_{t_j < t} \beta \exp(-\beta(t - t_j)). \quad (2)$$

The term $\alpha_{dd'}$ and the term $\beta \exp(-\beta(t - t_j))$ can be considered as the decomposition of kernel function $\phi_{dd'}$, which respectively describe the influence weight of dimension d on dimension d' (including α_{dd} , the self-excitation of dimension d itself) and an exponential decay function $g(t) = \beta \exp(-\beta(t))$. Putting together all activity types' parameters, we use a d -dimensional vector $\mu = [\mu_d]$ to represent the base rates of the processes in all dimensions, and a $d \times d$ matrix $\Phi = [\phi_{dd'}]$ to represent the between and within dimension triggering effects. From here, we can write $\Phi = I \circ G$, where we have *influence matrix* $I = [\alpha_{dd'}]$ and *exponential decay kernel* $G = [\sum_{t_j < t} (-\beta \exp(-\beta(t - t_j)))]$. Based on that, we can also describe the aggregated influence of dimension d on other dimensions using the following equation:

$$\alpha_d = \frac{1}{|\{d\}|} \sum_{d'} \alpha_{dd'}, \quad (3)$$

which is simply the average influence of dimension d over all dimensions. A summary of all notations used so far are shown in Table 1.

This intensity function $\lambda_d(t)$ has an intuitive meaning: all the future activities in dimension d , apart from those that are triggered by external stimuli, can be triggered by the previous activities that belong to each of the dimensions d' (including d itself) according to the influence weight $\alpha_{dd'}$ (the outer summation). The ones that are triggered by ex-

Notation	Description	Formula
L	Dimension module lectures	
A	Dimension module assignments	
D	Dimension module discussions

Table 1: Notations and their descriptions.

ternal stimuli take places with rate μ_d . Furthermore, as a past activity becomes distant (larger $t - t_j$), its effect on the occurrence probability of a new event decreases exponentially (i.e. the inner summation). From the branching process point of view, the kernel function $\phi_{dd'}$ is designed in this way so that $\alpha_{dd'}$ is the branching ratio. By computing $\frac{1}{1 - \alpha_{dd'}}$, we can obtain the expected number of future activities in dimension d' that are triggered by an immigrant in dimension d . This represents the size of an offspring cluster.

To avoid possible confusions, we also want to clarify that by saying one activity i in dimension d' *triggers* another activity j in dimension d , we mean that the probability of activity j in the result of activity i is higher than j coming from base rate μ_d or triggered by other activities. To see this, one can interpret Equation 1 as follows: in dimension d , a sequence of activities come from the base rate μ_d and each summation leads to a sequence of activities with parameter $\phi_{dd'}$. Then, the probability of j being triggered by i is

$$P(j \text{ child of } i) = \frac{\phi_{dd'}(t_j - t_i)}{\mu_d + \sum_{t_i < t_j} \phi_{dd'}(t_j - t_i)}. \quad (4)$$

Parameter Estimation. A common way to find the best parameters of Hawkes model, given the observed activity arrival times, is to minimize the negative log-likelihood of the data. Particularly, given the sequence $\{(t_i, d_i), \dots, (t_N, d_N)\}$ till some time T , the log-likelihood of having influence matrix I and base rate vector μ is of the following form:

$$\mathcal{L}(I, \mu) = \sum_{i=1}^N \log(\mu_d + \sum_{t_j < t} \alpha_{dd'} g(t_i - t_j)) - T \sum_{d=1}^n \mu_d - \sum_d \sum_{d'} \alpha_{dd'} \int_0^{T-t_j} \phi(T - t_j) dt_j. \quad (5)$$

In order to find Hawkes parameters that models each module-student pair, we adopted algorithm ADM4 [45], which made use of a mix of Lasso and nuclear regularization on top of the negative log-likelihood. Specifically, Accelerated Projected Gradient Descend method was used to meet the non-negative constraints on I and μ as Hawkes parameters only have realistic meanings when the parameters are non-negative⁵. When it comes to the selection of global parameter β , for

⁵We made our implementation available at <https://github.com/ssahebi/EDM2020-Hawkes>.

each module-student pair, we use grid search with cross validation on the interval $[0, 10]$ with step size 1.

6. EXPERIMENTS

6.1 Testing the Goodness of Fit

To test the goodness-of-fit of the model, in Table 2, we compare the RMSE of the intensity for all dimensions, computed based on the observed module-assignment pairs, for multi-dimensional Hawkes model (i.e. Equation 1), single-dimensional Hawkes model and a Poisson model. Specifically, for single-dimensional Hawkes, we treat all activities as in one dimension, and estimate the intensity of each dimension using the uni-variate parameters α , β , and μ . For the Poisson model, in each dimension, we use the average activity arrival rate as the base rate, and compute the RMSE for each dimension respectively. As we can see in

	L	A	D
Hawkes (Multi)	0.56	2.34	1.37
Hawkes (Single)	0.71	2.57	1.95
Poisson	3.22	6.91	3.73

Table 2: The goodness of fit to true data for each model in terms of intensity RMSE.

Table 2, Poisson has the worst fit in all dimensions, possibly caused by the non-Poissonian nature we showed from the real data. Single-dimensional Hawkes has comparable but slightly worse performance. One possible reason is that there might exist differences in terms of base rate and burstiness between dimensions and by modeling all types of learning materials as one activity type, the model can only capture the average trend in all dimensions. To visualize how the multi-dimensional Hawkes processes fit the real data, we also present in Figure 4 the estimated intensity (blue) and true intensity (black) of a sample module-student pair. As we can see in this figure, the model mostly has a good fit to the real data. Only at some time points, it underestimates the expected number of activities that are about to happen.

6.2 Model Parameter Analysis: Trends and Differences Between Dimensions

In this section, we analyze the estimated Hawkes parameters within and between different dimensions, to show their general trends and differences across different dimensions.

We start this part with a correlation analysis of all Hawkes Parameters, to show the general trends and possible differences between dimensions. Particularly, we calculate the Spearman rank correlation coefficients between the parameters that are learned for all module-student pairs as is shown in Figure 5. Recall that parameters $\alpha_{dd'}$, μ_d , β and α_d respectively is the between-dimension (or within if $d = d'$ excitation, base rate, decay rate (Equation 2) and aggregated influence of dimension d (Equation 3) for $d \in [L, A, D]$.

We can see that self-excitation within dimensions (i.e. α_{dd}) are generally negatively correlated with base rates μ_d of the same dimensions and decays β . This means that as the external stimuli leads to more and more expected arrivals, i.e. when regular activities come from the base rate, the effect of each previous activity on the future ones tends to decrease, i.e. self-excitation gets weaker. In other words, in

Figure 4: Estimated and true intensity of a sample module-student pair, modeled by multi-dimensional Hawkes.

sequences with higher regularity, less burstiness is observed. Also, it means that activities that have a slower decay rate usually arrive in a more bursty manner. Mapping to our application of students interacting with learning modules, by using the branching process point of view, higher α suggests higher expected number of activities in a latent cluster as sub tasks. On the other hand, the negative correlation also means a lower base rate and lower number of immigrants. In other words, the number of such latent clusters are also fewer. One possible interpretation is that in each dimension, students divide their big learning task into sub tasks and work for each individual sub task in a relatively bursty manner. This also suggests that students barely have behaviors that are both highly intense and highly frequent (i.e. large μ_d and α_{dd}). Similarly, both highly sparse and highly mediated activities (i.e. small μ_d and α_{dd}) are rarely observed neither, as the correlation between μ_d and α_{dd} is positive for all $d \in [L, A, D]$.

Comparing the parameter correlations across different activity types, we can see that dimensions L and D , have high within and between-dimension influence correlations. For example, the correlation between α_{LL} and α_{LA} is 0.97 in dimension L and correlation between α_{DL} and α_{DA} is 0.96. This implies that the influence of discussion and video lecture activities on other dimensions are almost consistent. For example, if the influence of video lectures on assignments is high, it is likely that the influence of video lectures on discussions is high too. Similarly, if the pattern of interacting with video lectures in a module is bursty (high α_{LL}), it is likely that other activity types triggered by video lectures are also bursty. However, the influence of assignment activities on discussions and video lectures are not significantly associated with assignment activity's self-excitement. That could mean that after a student has a bursty set of assignment activities in a module, the student is less likely to have

a bursty video lecture activities. Similarly, the influence of assignment activities on discussions has a low correlation with the influence of assignment activities on video lectures. For instance, if a student starts an assignment intensively very closely after some intensive watching of video lectures, the student is less likely to have high intense discussion activities after assignments. We can also see that assignment-triggered activities' burstinesses are less correlated with the base rates (i.e. α_{AD} vs. μ_d). This means that the frequency of activities that come from external stimuli does not affect the influence of assignment activities on consequent activities in other dimensions. Taken altogether, it is interesting to see that activities that are associated with assignments tend to have different exciting patterns compared to video lectures and discussions. This can show the influence of deadlines, as the assignments are the only activity type that have deadlines and are going to reflect student grades in this dataset.

Figure 5: Spearman Rank Correlation Coefficients between Hawkes Parameters.

6.3 Student Behaviors Characterized by Model Parameters

In the previous part, we were interested in showing the correlation between Hawkes parameters that represented within and the between-dimension relationships. In this part of the analysis, we focus on the different behaviors that are observed according to the learned parameters for each module-student pair. Additionally, we are interested to see if these learned Hawkes parameters are proper representatives for student procrastination. To do so, we first define a measure that can represent student procrastination in the absence of self-reported data. In the following, we go over some important assumptions, definitions and time measures that we use for procrastination.

Defining Delay as a Procrastination Measure. We assume that each student works on one module at a time, meaning that they do not work on several modules at the same time. Furthermore, we assume that submitting the last attempt of the module's assignment marks the end of study-

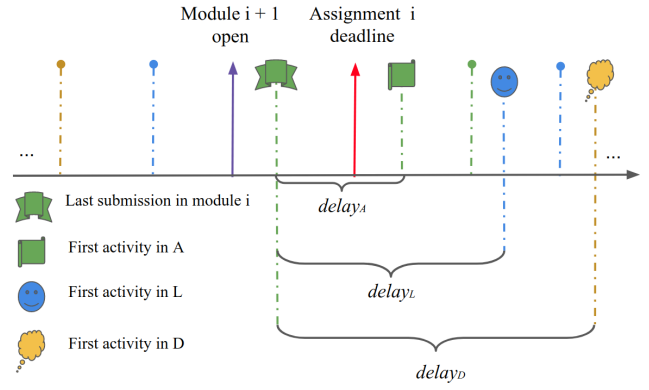

Figure 6: Illustration of delay measures. As in Figure 3, we use blue, green and yellow dashed lines to represents activities from dimension L, A and D respectively.

ing this module. According to these assumptions, we define module i 's end time for student j , t_{ij}^e as the time stamp when the last module assignment was submitted. We then define the start time t_{ij}^s as the earlier time stamp between $t_{i-1,j}^e$ and the available time for module i . In other words, when student j finishes learning module $i-1$, if module i has already been made available, then their end time on module $i-1$ is defined as the start time for module i . Otherwise, the start time is going to be the time when module i becomes available or is published online. In each dimension d , we use t_{ij}^d to denote action time, which is defined as the time that the first activity in dimension d takes place between start time t_{ij}^s and end time t_{ij}^e .

Having the module start time and student action time in dimension d , we can calculate how late a student started working on activity of type d in the module using $t_{ij}^d - t_{ij}^s$. To factor in the duration differences between different modules, we normalize this value by the module duration. Eventually, we define the following measure to quantify student j 's normalized delay in dimension d that is associated with module i :

$$delay_d = \frac{t_{ij}^d - t_{ij}^s}{t_{ij}^e - t_{ij}^s} \quad (6)$$

One of the motivations to define the delay according to start time t_{ij}^s is that, sometimes module $i+1$ is available before the assignment deadline in module i . By this time, student j might still be working on module i . So, it would be unfair to count the time after module $i+1$ is available and before student j 's assignment submission as the procrastinating time for student j on starting module $i+1$. On the other hand, if student j finishes the assignment in module i earlier than the deadline of the assignment, this extra time they earned from the early submission can be used toward the next available module. If the student does not use this time, it will be considered as a cramming behavior toward the next module $i+1$. An illustration of these definitions is presented in Figure 6.

Observing Two Behavior Groups. We now focus on the distribution of the learned Hawkes parameters to see if we can observe any behavioral patterns across different student-module pairs. Specifically, in Figure 7 we present

the distribution of the learned α_{LL} , α_{AA} , and α_{DD} . We can clearly observe two spikes in the density distribution of influence parameters, more prominently in α_{LL} and α_{AA} . Combining this observation with the correlation analysis in previous section, we can see that there are two types of module-student interactions: the ones with higher frequency and lower burstiness versus the ones with lower frequency and higher burstiness. To statistically show the dif-

Figure 7: Density distribution of α_M , α_A , α_D .

ference between these two types of interactions, we first cluster student-modules according to their α_{LL} and α_{AA} , into two groups using the K-means clustering algorithm. Then, we test to see if the learned Hawkes parameters, i.e. excitation parameters $\alpha_{dd'}$, base rate μ_d , decay β and aggregated influence α_d for $d \in [L, A, D]$, are statistically different across the two groups. Particularly, we conduct the Kruskal-Wallis test on each learned parameter between the two clusters. The average values of the parameters for each of the two clusters are shown in Table 3. Since the p-values for all tests are smaller than 0.0001, we do not show them in the table. These small p-values suggest that the differences between clusters are statistically significant for all parameters between the two types. This indicate that the differences between the two types are meaningful.

Examining both groups more closely, we can see that, the aggregated influence of dimension A, i.e. α_A , is the highest among all 3 for both type 1 and type 2 groups. With that being said, this influence majorly comes from the self-excitement in dimension A, i.e. α_{AA} . μ_A is also the highest among all 3 dimensions. Combining these observations, we can see that assignment-related activities arrives more frequently and are highly influential in triggering consequent activities, especially the assignment-related ones. Also, we can see that on average type 2 group has a much smaller base rate for video lectures (μ_L) and discussions (μ_D), meaning less density and regularity in those activities compared to type 1. However, In assignment-related activities, the base rate (μ_A) as well as aggregated influence in dimension A (α_A), are higher in type 2 group, which suggests an overall denser and more intense assignment-related activities arrivals comparing to type 1 group.

Now if we look at the differences between two groups in terms of between-dimension relationships, we can see that α_{AL} , i.e. the triggering effect of assignment to consequent video lecture activities (and similarly, α_{AD} : the assignment-triggered discussion activities) is much lower in type 1 group compared to type 2 group. This difference is also notable

in other between-dimension α s. For example, the influence of assignments on video lectures (α_{AL}) is way less than the influence of video lectures on discussions (α_{LD}) in type 2 group, while this difference is less in the type 1 group. This suggests that the interaction patterns with assignments in type 2 group are almost inconsistent with other dimensions. We note that, although the type 1 and type 2 clusters are created according to α_{LL} and α_{AA} parameters only, we see significant differences in all other parameters of the two groups.

Delay in the Discovered Groups. Here, we aim to understand if the two behavior types that we discovered in the previous part are associated with measures of procrastination. Particularly, we evaluate the differences observed in the delay measures defined in Equation 6 for the two clusters. The results are presented in Table 4. Again, all p-values are smaller than 0.0001. A major observation is that type 1 and type 2 have very different delays in all dimensions. Specifically, the delay of each dimension in type 1 group is much less than the corresponding delays in type 2 group. As a result, we can call type 2 group as the delay group and type 1 group as the non-delay group. Given that the type 1 and type 2 behavioral clusters are formed based on Hawkes model parameters only, this important observation demonstrates that the learned Hawkes parameters can clearly represent delay as a procrastination measure. Also, we can see that in delay (type 2) group, on average, students start the first discussion way after the first assignment activity takes place ($delay_D > delay_A$). However, in the non-delay (type 1) group, on average the first assignment activity happens after some discussion ($delay_D < delay_A$). We can see that in both groups, the video lecture activities come before discussions or assignments.

Combined with our observations from the previous analysis, we see that not only the delay group start the first activity in each dimension much later than the other group, they also have a much less base rate μ_L and μ_D . Consequently, we can see that the delay group (type 2) has less frequent but more bursty discussion and lecture-related activities, while the non-delay group activities arrive in a less bursty but more frequent manner in these two dimensions. On the other hand, assignment activities are denser and more intense for the delay group. This combined observation shows that the Hawkes parameters can represent more information about student procrastination, compared to the delay measure alone.

6.4 Student Grades Associated with Model Parameters

In the previous section, we concluded that the learned Hawkes model parameters not only represent delays, but also can capture more procrastination-related behaviors. In the rest of this section, we are interested in exploring if the additional trends captured by the Hawkes model can be more meaningful in association with student grades, compared to the delay parameter. In particular, we are interested in the association between delay and student grades from the Hawkes processes point of view.

Recall that $delay_d$ defined in Equation 6 measures the normalized delay of the first activity in dimension d of the

	d	α_{dL}	α_{dA}	α_{dD}	α_d	μ_d	β
Type 1	L	0.558±0.149	0.263±0.178	0.289±0.185	0.381±0.524	0.0003±0.0006	0.663±0.692
	A	0.107±0.272	0.820±0.125	0.101±0.264	0.462±0.459	0.0003±0.002	
	D	0.322±0.393	0.305±0.393	0.790±0.151	0.394±0.325	5.52E-5±1.8E-4	
Type 2	L	0.874±0.108	0.823±0.135	0.816±0.134	0.795±0.582	4.82E-5±9.86E-5	0.425±0.249
	A	0.019±0.124	0.864±0.061	0.018±0.124	0.799±0.582	0.0004±0.004	
	D	0.699±0.429	0.696±0.430	0.936±0.092	0.590±0.238	1.19E-5±5.92E-5	

Table 3: Statistics of Hawkes parameters $\alpha_{dd'}$, μ_d , β and α_d for $d \in [L, A, D]$ in the two clusters.

	$delay_L$	$delay_A$	$delay_D$
Type 1	0.08±0.228	0.575±0.411	0.338±0.385
Type 2	0.108±0.274	0.722±0.360	0.819±0.337

Table 4: Statistics of delay measures $delay_L$, $delay_A$ and $delay_D$ in two clusters identified by Hawkes parameters.

student-module pair. Here, we define a new delay measure based on both learned parameters of the Hawkes process and $delay_d$. We then study if this newly defined delay measure performs better in association with student grades, compared to $delay_d$. Specifically, after showing the between-dimension excitation interrelationships, it is reasonable to assume that these interrelationships are important in the activity delays as well. For example, knowing that assignment-related activities can trigger followup activities in all 3 dimensions, delaying the assignment-related activities also potentially causes consequent delays in other dimensions. Motivated by this, we propose $delay_d^H$ by combining $delay_d$ and between-dimension Hawkes parameters as follows:

$$delay_d^H = delay_d + \frac{1}{\sum_{d' \neq d} \frac{1}{1-\alpha_{dd'}}} \quad (7)$$

As we mentioned in Section 5, $\frac{1}{1-\alpha_{dd'}}$ can be seen as the statistically expected number of activities in a latent cluster that are triggered by an immigrant. The second term in Equation 7 basically quantifies the potential loss per time unit in terms of triggering other dimensions' activities by delaying in dimension d . Taken altogether, $delay_d^H$ describes the total delays in all 3 dimension that are associated with delay in dimension d .

To see if $delay_d^H$ provides more grade-related information compared to $delay_d$, we look at the Spearman's correlation between these two measures and students' assignment grades. The result of this correlation analysis is presented in Table 5. Our first observation is that the correlations between both delay measures with student grade are negative. However, this correlation is not as significant for $delay_d$, compared to $delay_d^H$. This is specially stronger in the assignment dimension. The reason for this can be two-fold: (1) comparing to $delay_d$, $delay_d^H$ not only captures how late the action was taken in each dimension, it also provides some insights on the student behavior trends throughout their learning process, and (2) as $delay_d^H$ describes the time-dependencies between dimensions, it is more powerful in explaining student activities in all dimensions as a whole, compared to the point estimate summaries of procrastination. Particularly, one may overlook the importance of delaying the discussion-related activities on assignment grades when considering the $delay_D$ measure only. However, a stronger correlation between $delay_D^H$ and grades suggests that early start of the discussion-related activities is almost equally important as starting the video lectures early, probably because of the triggering effect of dimension D and the

d	L	A	D	avg.
$delay_d^H$	-0.339***	-0.125*	-0.329***	-0.264**
$delay_d$	-0.240**	-0.070.	-0.114*	-0.141*

Table 5: Spearman's correlation with respect to assignment score for each delay measure. Significance level is denoted as follows: $p < 0.001$ * $p < 0.01$ ** $p < 0.05$ * $p < 0.1$.**

potential loss that its delay causes to all 3 dimensions.

7. CONCLUSION

In this work, we proposed to use the multi-dimensional Hawkes processes to model procrastination in student learning behavior. We showed that multi-dimensional Hawkes processes have a better fit to student activity counts in comparison with their single-dimensional version and the Poisson processes. By analyzing the correlations between the learned parameters in the Hawkes processes, we concluded that more bursty student sequences have less regular activities in them, the burstiness of video lecture and discussion-related activities vary similar to each other, and the deadlines highly affect the arrival times of assignment-related activities. We showed that Hawkes parameters can reveal two types of behaviors in the data that are associated with different delays - the delay group tends to have high within and between-dimension excitation but low base rate, and the non-delay group have a high base rate and a lower excitation in all dimensions. According to the branching processes point of view, we gave a realistic interpretation on these types of behaviors: non-delay group divide big tasks into many sub-tasks (high base rate) which leads to more frequent and less dense activities throughout the learning process. On the other hand, delay group tend to intensively work in one dimension for a shorter period of time, followed by long pauses (high excitation but low base rate). We also showed that the Hawkes model parameters represent richer information compared to the delay measure alone by defining a new Hawkes-based delay measure and associating it with student grades. Our experiments demonstrated that the between-dimension dependencies in the multi-dimensional Hawkes model better explain student grades.

This study is limited in the number and variety of the datasets that we have experimented on. In the future, we plan to explore more datasets from various disciplines and platforms. Another limitation is the single measure that we use to evaluate procrastination ($delay_d$). As a followup to this study, we aim to define and use more procrastination indicators, including the self-reported procrastination measures.

ABSTRACT

In higher education, predictive analytics can provide actionable insights to diverse stakeholders such as administrators, instructors, and students. Separate feature sets are typically used for different prediction tasks, e.g., student activity logs for predicting in-course performance and registrar data for predicting long-term college success. However, little is known about the overall utility of different data sources across prediction tasks and the fairness of their predictions with respect to different subpopulations. Using data from over 2,000 college students at a large public university, we examined the utility of institutional data, learning management system (LMS) data, and survey data for accurately and fairly predicting short-term and long-term student success. We found that institutional data and LMS data both have decent predictive power, but survey data shows very little predictive utility. Combining institutional data with LMS data leads to even higher accuracy than using either alone. In terms of fairness, using institutional data consistently underestimates historically disadvantaged student subpopulations more than their peers, whereas LMS data tend to overestimate some of these groups more often. Combining the two data sources does not fully neutralize the biases and still leads to high rates of underestimation among disadvantaged groups. Moreover, algorithmic biases affect not only demographic minorities but also students with acquired disadvantages. These analyses serve to inform more cost-effective and equitable use of student data for predictive analytics applications in higher education.

1. INTRODUCTION

The most common application of learning analytics in higher education is using predictive modeling to understand critical factors contributing to student success, or to identify students who need support in a timely manner. Predictive analytics have been used within a course [2] or while using tutoring software [38]. They have also been used to optimize student success in the longer term, for example to predict graduation rates [3] or to make course recommendations [26]. Different data sources can be used to build these predictive models, with varying trade-offs. For example, when making predictions at the course level, log data from learning management systems (LMS) are often used. These systems allow for automated and scalable recording of hundreds of learner actions in every single minute, but they require robust and efficient data management systems. When making longer-term predictions, on the other hand, institutions can use data typically stored in student information systems (SIS), including prior academic history, standardized test scores, and demographic information. While this data source might be readily available to college administrators, it might be more difficult to access, due to ethical concerns or logistic barriers, for individual instructors or researchers trying to build such models for particular use cases. In some cases, both data sources are further combined with assessments or surveys that measure students' metacognitive abilities or other non-cognitive attributes that might predict college success [35]. However, collecting and managing these data is often costly for institutions if they are not already doing so. Given all these trade-offs, it is necessary to examine the utility of different student data sources for building predictive analytics-based solutions to guide instructors, administrators and education policy makers on the costs and benefits of utilizing different data sources.

To date, research that systematically compares data sources and predictions is underrepresented in the literature [14]. To respond to this call for research, this study evaluates the usefulness of three common student data sources for two representative prediction tasks. These three data sources, including institutional data, LMS data, and survey data, are all widely used across research settings and have been shown to predict various measures of college success. Given the different use cases of short-term and long-term predic-

Renzhe Yu, Qiujie Li, Christian Fischer, Shayan Doroudi and Di Xu "Towards Accurate and Fair Prediction of College Success: Evaluating Different Sources of Student Data" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 292 - 301

tions as discussed above, we construct two success measures: individual course grades (short-term success) and yearly average GPA (long-term success). The usefulness of each data source is determined by its contribution to overall prediction accuracy and to prediction fairness across student subpopulations. The focus on fairness arises from the concern that predictive models trained on the entire student population may perform systematically worse on selected subpopulations than other others, which may have unintended negative effects for vulnerable students [6]. For instance, if models are less confident in identifying struggling students among an already underrepresented group, this bias may eventually amplify existing achievement gaps.

In short, our research aims to identify what combinations of student data (a) more accurately predict different success measures; and (b) more fairly predict these measures. The remainder of this paper is organized as follows: Section 2 summarizes the related work on college success prediction and fairness of predictive models; Section 3 describes the data and methods we use to construct and evaluate prediction models; Section 4 presents the results from various predictions; Section 5 reflects on the findings and discusses the practical implications for stakeholders; Section 6 concludes the study with limitations and future work.

2. RELATED WORK

2.1 Predicting College Success Using Student Characteristics

Although college is a complicated ecosystem with numerous factors shaping student outcomes, prior research has identified several groups of student characteristics across institutional data, LMS data, and survey data that consistently predict commonly used measures of success.

2.1.1 Personal Background - Institutional Data

Student success in higher education is often stratified by students' demographic, socioeconomic and academic background prior to college experience. For example, college graduation rates substantially differ by students' race/ethnicity. National data indicates that Hispanic students are 15% less likely to graduate college within six years than their white counterparts, and this gap is 25% between black and white students [33]. Such inequalities are particularly pronounced in STEM fields, where even more underrepresented students drop out of their college careers [1]. Also, student performance prior to entering college (e.g., on standardized tests) has often been found to strongly predict college performance across different subpopulations [9]. These overall trends suggest that what happens before college remains predictive of student success in higher education settings. Of course, this could be due to a variety of factors, such student background being correlated with patterns of historical and institutionalized oppression as well as other barriers that students from different backgrounds might face both before and during college.

2.1.2 Learning Behavior - LMS Data

In contrast to latent psychological states, learning behavior is a more extrinsic and observable predictor of academic success [7]. Behavioral patterns capture variations in college experience that may be orthogonal to students' incom-

ing characteristics, allowing for insights into the mechanism of academic success at a day-to-day granularity. With the prevalence of digital learning platforms, learning behavior can be authentically recorded in the form of clickstream data. These time-stamped data record learner's interactions with LMSs. This allows researchers to create measures that look into the "black box" of study behaviors [5]. For example, how students allocate their study time is a consistent predictor of performance. Those who have more regular engagement patterns and who space out their study effort (instead of cramming) are more likely to be high-achieving [27]. Similarly, students who strategically regulate their learning effort (e.g., starting from exercise-oriented tactics and moving to other tactics based on encountered challenges) perform equally well but with less effort, compared to simply hard-working students [23].

2.1.3 Non-Cognitive Abilities - Survey Data

There is emerging evidence that non-cognitive factors, such as personality traits, task values and self-efficacy, are associated with positive academic outcomes even after controlling for cognitive factors measured by intelligence tests as well as various background characteristics [8]. Among these factors, researchers seem to have reached consensus that self-regulated learning skills are essential because unlike in K-12 schooling, college students have the flexibility as well as responsibility to actively and constantly monitor, reflect on, and adjust their motivation, cognition, and study behavior [37]. To better describe and measure a student's ability to regulate their learning process, [29] divided it into three subcomponents with two cognitive components (the use of cognitive strategies and the use of metacognitive strategies) and one non-cognitive component (resource management, including skills of time and study environment management, effort regulation, peer learning, and help seeking). A systematic literature review focused on online learning contexts found consistent evidence that resource management skills, especially time management skills and effort regulation skills, are predictive of performance [10]. While new technologies are creating novel measurement tools for these intangible qualities, the "ground truth" mostly comes from validated surveys.

2.2 Comparison of Different Data Sources

Previous work has examined combining various data sources for predictive analytics in higher education. For example, [2] combined institutional data, course performance data and LMS data to predict students' within-course success. However, there has been little work comparing the impact of various data sources on student success. [3] compared the impact of different types of institutional variables, including demographic variables, prior academic achievement, student majors, and academic achievement in college courses on predicting graduation and re-enrollment rates. [36] compared the impact of virtual learning environment (VLE) data, course assessment data, and a demographic variable on predicting whether a student's performance will drop in a course and whether a student will pass or fail a course. They generally found that using VLE data in conjunction with assessment data was seemingly better than using either alone. In what is perhaps the closest study to ours, [35] compared the impact of learning behavioral features, student background, and non-cognitive features measured

by a socio-emotional skill assessment on predicting within-course success. Our study differs from theirs in that we look at long-term outcomes as well as short-term outcomes, we analyze the fairness of predictive models, and we fit models that span across several courses.

2.3 Fairness of Predictive Analytics in Education

In recent years, the fairness and biases of machine learning algorithms and systems have developed into a focused research area in the general machine learning research community¹. Research efforts encompass developing statistical measures of fairness, evaluating existing algorithms/systems, and correcting for biases in algorithmic pipelines, among others. As fairness is a concept rooted in a variety of disciplines, it has been a consensus that there is no single “correct” definition of fairness. Rather, what is fair is highly dependent on the specific application scenarios [6]. As such, contextualizing the fairness research in different fields is critical to improving real-world applications.

In earlier education research, there has been a focus on heterogeneous effects across student subpopulations in the contexts of testing [34], observational studies [39] and program evaluation [31]. These earlier perspectives resonate with the current theme of fairness, but as the adoption of predictive analytics systems in education for high-stakes purposes has a comparatively shorter history, formalized research on fairness in such contexts has been somewhat limited. Among the handful of empirical papers that have directly evaluated this aspect of predictive analytics in education, [13] showed through a simulation study that misspecified student models in intelligent tutoring systems could leave “slow” learners at lower mastery levels than “faster” learners; [16] examined the ROC curves from MOOC dropout prediction models, and identified significant gaps between gender groups through slicing analysis; and [19] used college application materials to predict on-time graduation and, employing the same slicing analysis, concluded that their model could make fair predictions across five sociodemographic groups.

As [6] points out, while the biases of predictive systems may be attributed to unfair algorithms, they can also arise from biased data which “reflect historical prejudices against certain social groups, prevailing cultural stereotypes, and existing demographic inequalities”. Therefore, unlike the previous studies described above, this paper examines fairness as an attribute of *data sources* rather than of *algorithms*. We look at fairness with respect to between-groups differences in three metrics: accuracy, false positive rate, and false negative rate. These metrics are among the many fairness metrics that have been proposed in the literature [6]. For example, having an equal false negative rate between subgroups has been called “equality of opportunity” in the context of giving everyone an equal opportunity to receive a positive intervention (e.g., being part of the university’s honor roll for having a high GPA) [17].

3. DATA AND METHODS

3.1 Data Sources

¹<https://facctconference.org/>

Following Section 2.1, this study compares the three widely available data sources in higher education settings: institutional data, Canvas LMS log data, and survey data. Specifically, we drew the sample of all students who enrolled and received final grades in ten fully online, introductory STEM courses taught from 2016 to 2018 at a large, public research university in the United States. Six of the courses were in public health while the remaining four were distributed across biology, chemistry and physics. These courses were the subject of a large research project, where our research team administered a series of standard survey questions about students’ motivation, self-regulation and other psychological constructs before, during and/or after each course. Therefore, we had valid survey data across multiple courses. Also, looking at online courses ensured that LMS data can provide holistic representations of learning behavior. A total of 2,244 students were in the original dataset, and after data cleaning as described below in Section 3.2, the final sample size was 2,093. Traditionally underrepresented groups in STEM fields made up a large portion of the sample: 72% were female, 48% came from low-income families, 54% were first generation college students, 33% were underrepresented minorities (URM)², and 13% were transfer students.

3.2 Features and Outcomes

From each of the three data sources, we constructed a separate feature set in line with the literature. Table 1 gives a summary of these features. *Institutional features* included student demographics and academic achievement prior to college. *Click features* were derived from the LMS data and only included general measures of behavioral engagement to accommodate the variances in course design. Specifically, for each student in each course, we calculated the total number of clicks and total time spent over the first half of the course period. Time spent was calculated as the time lapse between adjacent click events. For the last click event of a student (with no subsequent event) or exceptionally lengthy lapses, we set a heuristic value of 90 seconds. The click counts and time spent were also broken down by categories, which were defined based on the URLs that click events pointed to, including “portal”, “tasks”, “content”, “communication”, “performance” and “miscellaneous.” Restricting to the first half of course period speaks to the scenario of early identification of at-risk students for instructors. *Survey features* included four constructs of self-regulated learning skills and self-efficacy [29] from pre-course surveys launched during the first week of these courses. The completion rates of these surveys ranged from 65% to 93% across the ten courses. All survey items were adapted from Motivated Strategies for Learning Questionnaire (MSLQ), a popular questionnaire to measure self-regulation skills in online learning [30]. Each of the four constructs was measured by the average of corresponding survey items (Table 2).

As for outcomes, we defined two success measures. *Short-term success* was defined as a binary indicator of whether a student’s final course grade was above the class median. Predicting this within-course outcome aligns with the needs of instructors to recognize struggling students in a timely manner [15]. Similarly, *long-term success* was defined as

²This includes African American, Hispanic, and Native American students.

Table 1: Features derived from the three data sources

Institutional	Click	Survey
Female	Total clicks	Effort regulation
Transfer	Total clicks by category	Time management
Low income	Total time	Environment management
First-gen	Total time by category	Self-efficacy
URM	(All above for the first 5 weeks)	
SAT total score		
High school GPA		

Table 2: Details of survey features. Each feature was calculated as the average of its associated items.

Feature	Items (5-point Likert scale)
Effort regulation	I often feel so lazy or bored when I study that I quit before I finish what I planned to do (reverse coded). I work hard to do well in courses even if I don't like what I am doing. When coursework is difficult, I give up or only study the easy parts (reverse coded). Even when course materials are dull and uninteresting, I manage to keep working until I finish.
Time management	I keep a record of what my assignments are and when they are due. I plan my work in advance so that I could turn in my assignments on time.
Environment management	I usually work in a place where I can read and work on assignments without distractions. I can ignore distractions around me when I study.
Self-efficacy	I'm certain I can master the skills taught in this course. I'm certain I can figure out how to learn even the most difficult course material. I can do almost all the work in class if I don't give up.

whether a student's average GPA in the year that followed the course was above the median of their classmates in that course. Predicting this longer-term outcome is of interest to academic advisors and institutional policymakers because it can help them make appropriate policy changes early in students' academic careers to increase student success and graduation rates [22]. We used class medians to construct these outcomes instead of certain grade thresholds in order to better compare short-term and long-term results.

We examined all possible combinations of the three feature sets ($2^3 - 1 = 7$) regarding their ability to predict the two success measures. Therefore, a total of 14 binary classification problems were formulated. To fairly compare the prediction performance of these feature sets, students with missing values on more than 25% of all the individual features in Table 1 were dropped, which accounted for the decrease in sample size from 2,244 to 2,093. All continuous numerical features were standardized by centering to the median and scaling according to the interquartile range (IQR) to better handle outliers. For the remaining missing values, we performed multivariate imputation, i.e., modeling each feature with missing values as a function of other features.

3.3 Predictive Models

For each classification problem, we employed three common classification algorithms: logistic regression, support vector machines (SVM), and random forests. Course-level leave-one-group-out cross validation was used. In other words, the algorithm looped through the ten courses, and in each iteration used one course as the test set for the model trained on the remaining nine courses. Predicted values for each course were then put together from the ten iterations to evaluate the overall prediction performance. As our focus was the predictive power of different feature sets instead of models, we chose the classifier that produced the highest F-score for each combination of feature set and outcome.

Because we used median splits to construct outcomes, class imbalance was not a concern and therefore no resampling was performed. The entire predictive modeling process was implemented using the scikit-learn Python library [28].

3.4 Evaluation

We evaluated the prediction results via three metrics. Accuracy measures the overall predictive power of the features used. False positive rate (FPR) reflects the probability of missing out "at-risk" students or "overplacing" students. False negative rate (FNR), on the other hand, captures the chances of "underplacing" students [32]. These metrics can shed light on potential consequences of using certain data source(s) in different applications. From there, we can compare the utility of different data sources in a holistic manner.

We further evaluated each data source's contribution to the fairness of prediction results. Fairness was conceptualized as the performance parity across student subpopulations when the prediction was performed on the entire student sample. Specifically, we focused on an array of historically disadvantaged subpopulations and compared each of them with a corresponding reference group on the three metrics. For example, we compared the accuracy, FPR and FNR within Latinx students with those within white students. Figure 1a and 1b plot the group size and outcome distribution of these selected groups, where the last group under each category was the reference group.

Statistically, we computed the following disparity metrics for each disadvantaged group g :

$$acc_disparity = acc_{ref}/acc_g \quad (1)$$

$$fpr_disparity = fpr_g/fpr_{ref} \quad (2)$$

$$fnr_disparity = fnr_g/fnr_{ref} \quad (3)$$

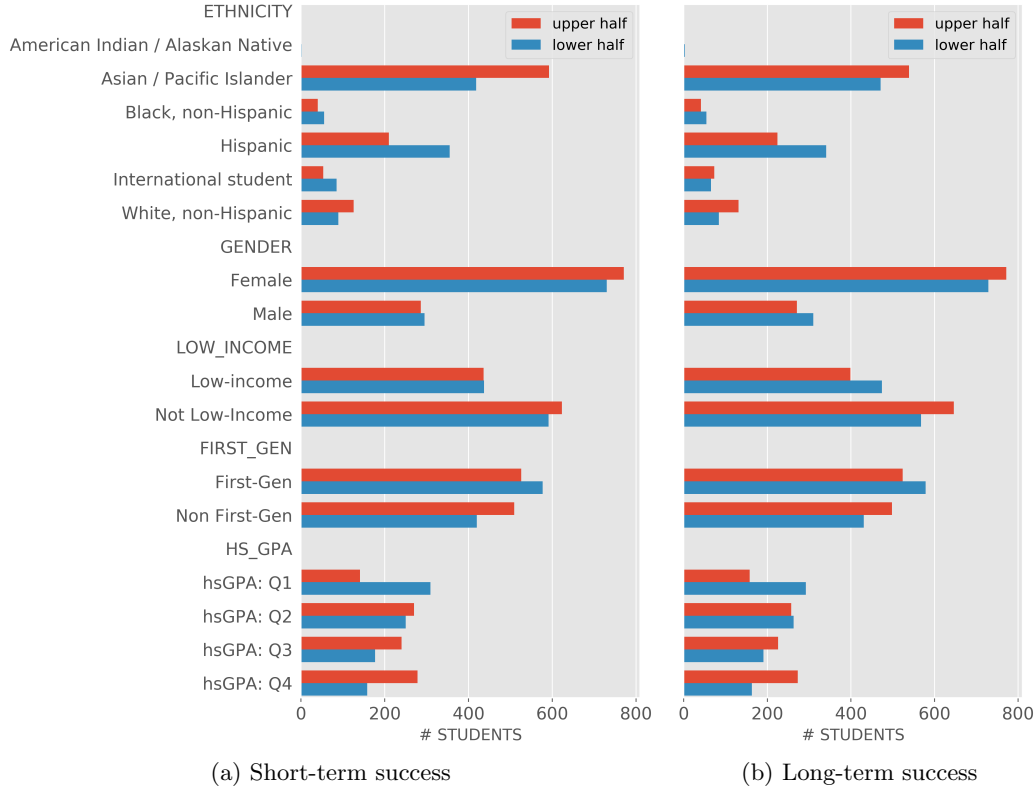

Figure 1: Outcome distribution within different student subpopulations. Short-term success: whether a student’s final course grade was above the class median. Long-term success: whether a student’s average GPA in the following academic year was above the class median.

and separately tested whether each of this disparities was significantly larger than 1 using one-sided two proportion z-test. The larger these ratios were, the more this student group was “discriminated against” by the prediction model. We used the less flexible one-sided test because of the consistent evidence that traditionally underrepresented groups experience more inequities than their counterparts in academic settings [1]. All these ratios combined would characterize the comparative utility of different data sources for fair predictions of college success.

4. PREDICTIVE UTILITY OF DIFFERENT DATA SOURCES

4.1 Overall Prediction Performance

Table 3 presents the prediction results on our full student sample across different feature and outcome combinations. In each column, the best-performing model is in bold to indicate which feature set(s) best predicted the corresponding outcome in the column header in terms of the given metric. Among the final sample of 2,093 students, 1,062 (50.7%) had short-term and 1,048 (50.1%) had long-term outcomes above their class median³. These numbers serve as the naïve baselines of prediction accuracy where all the students were simply predicted to be in the upper half (majority class).

³The slight deviation from 50% was due to the drop of students with too much missing information on predictors, as described in Section 3.2.

When the three data sources were used separately, institutional features and click features both achieved an overall accuracy of around 0.6 for either short-term or long-term outcomes, which was significantly higher than the baseline ($p < 0.001$ for all four cases). Specifically, institutional features appeared to be slightly more predictive of short-term success and click features predicted long-term success a little better, but neither of these comparisons was statistically significant. On the contrary, survey features had much weaker predictive utility because they predicted both outcomes with significantly lower accuracy than the worse of the other two features ($p < 0.001$ for short term and $p = 0.005$ for long term). When these feature sets were combined in different ways, we mostly saw improvement in the overall accuracy. The combination of institutional and LMS data led to the most noticeable accuracy increase in predicting both outcomes ($\Delta = 0.052, p < 0.001$ for short term and $\Delta = 0.037, p = 0.014$ for long term), evidencing complementary signals of student success in these two data sources. Survey data provided limited marginal utility as adding survey features to other feature sets never led to a statistically significant increase in accuracy and sometimes even had negative effects. However, the highest accuracy in predicting the short-term outcome was achieved when all three feature sets were used together.

Given the tradeoff between false positives and false negatives, overall best-performing feature sets did not necessarily

Table 3: Prediction performance on the entire student sample ($N = 2,093$). The best result in each column was in bold. Short: predicting whether a student’s final course grade was above the class median; long: predicting whether a student’s average GPA in the following academic year was above the class median.

Feature	Accuracy		FPR		FNR	
	Short	Long	Short	Long	Short	Long
Institutional	0.618	0.599	0.467	0.412	0.299	0.389
Click	0.602	0.613	0.485	0.385	0.313	0.389
Survey	0.534	0.557	0.599	0.385	0.336	0.502
Institutional+Click	0.670	0.650	0.351	0.330	0.310	0.370
Institutional+Survey	0.633	0.608	0.398	0.397	0.337	0.386
Click+Survey	0.609	0.604	0.431	0.457	0.353	0.335
Institutional+Click+Survey	0.675	0.638	0.348	0.402	0.303	0.323

have the lowest error rates. Among the three cases using a single data source, institutional features had both the lowest FPR and the lowest FNR for the short-term outcome ($p = 0.402$ for FPR and $p < 0.001$ for FNR compared to the second lowest). The same features also tied with click features for the lowest FNR in predicting the long-term outcome, while the latter led to the lowest FPR in the long term (tied with survey features). Combining these two data sources significantly lowered FPR ($\Delta = -0.116, p < 0.001$ for the short term and $\Delta = -0.055, p = 0.009$ for the long term) but not FNR. As for survey data, the patterns of error rates were more complicated than of overall accuracy. When used alone, survey features mostly led to higher error rates than the other two feature sets, except for FPR in the long term. On the other hand, adding survey features to other feature sets largely decreased FNR for long-term and FPR for short-term success predictions despite the fact that these metrics were exceptionally high in the case of using survey data alone.

4.2 Fairness of Predictions

Following Section 3.4, we computed and tested the extent to which each disadvantaged student subpopulation suffered discriminatory predictions (i.e., algorithmic bias) compared to their reference group under each combination of feature set and outcome. Figure 2a and 2b illustrate these results for short-term and long-term success prediction, respectively. Each cell colors a bias against a certain student subpopulation in a specific model. Darker cells suggest larger biases and crossed out cells represent those that were statistically significant ($p < 0.05$) after correcting for multiple testing within each background attribute. Subpopulations with fewer than 10 students were omitted as the error rates were less reliable.

Overall, there was no feature set that was entirely free from biased predictions. Across both outcomes, institutional features consistently led to higher FNR within various disadvantaged student subpopulations than within their peers. In other words, these students were more likely to be *underestimated* by the prediction model. This finding resonates with previous research that being aware of protected attributes (e.g., ethnicity) might induce identity-based biases in predictive analytics [6]. Adding other features to institutional ones alleviated some of these biases only in a marginal sense. That is, inclusion of institutional features seemed to largely determine the discriminatory behaviors of the model. Identity-blind LMS data was a fairer data source as the num-

ber of discriminated subpopulations was smaller. Compared to their reference groups, click features on their own significantly *overestimated* female students for both outcomes and Asian, Hispanic and first-generation college students for the long-term outcome. Survey data turned out to be neither accurate nor fair. When used alone, survey features led to significant biases against certain subpopulations across all metrics and outcomes. When combined with other feature sets, they did little to offset existing biases in most cases, except when they were used together with click features to predict long-term success. However, this latter case may suggest that survey data had equally low predictive utility for long-term success across different student subgroups.

The plots also allowed for insights into the extent to which different student subpopulations were exposed to algorithmic biases across different scenarios. Ethnic minorities, students from low-income families and first-generation college students were more prone to underestimation. Female students were more likely to be overestimated than male students especially in the long term. Moreover, international students and students with lower high school GPAs suffered both more underestimation and less accurate predictions compared to their peers. Note that unlike other variables in the plots, high school GPA is an acquired attribute. Hence, our evidence of algorithmic bias implied that a student can be stigmatized due not only to their demographic attributes but to their past (academic) experience as well.

4.2.1 A Closer Look into Institutional Data

Reflecting on the consistent biases against disadvantaged student subpopulations when using institutional data, we also tested if removing a specific institutional feature (e.g., gender) would eliminate the bias against the corresponding disadvantaged group (e.g., female). Surprisingly, all the results looked qualitatively similar regardless of which feature we removed. This suggested the intersectionality of minority identities, i.e., a student from one disadvantaged group tended to have another disadvantaged characteristic as well. As such, simply removing individual background variables would not necessarily make the predictions fairer.

5. DISCUSSIONS

5.1 Reflections on the Results

Our results shed light on the predictive validity of different sources of student data on college success. Our overall results agree well with those of [35], where features from an

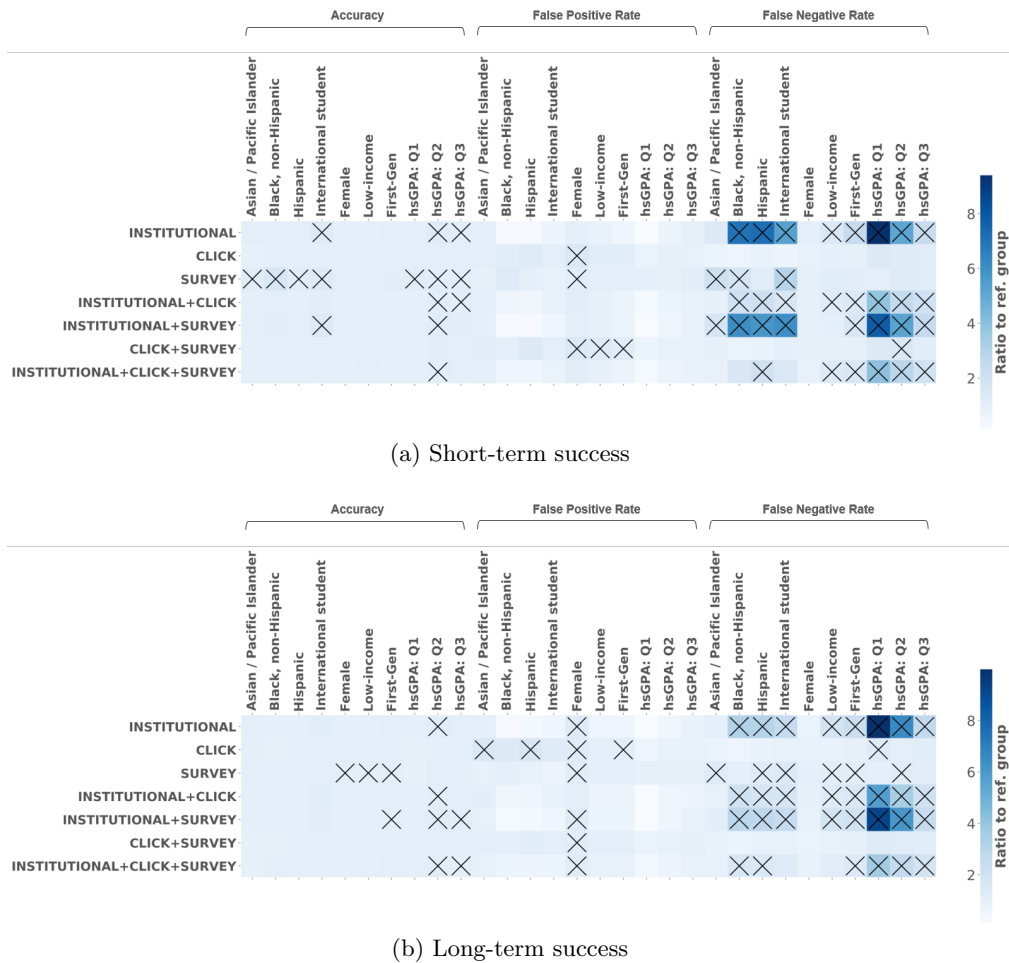

Figure 2: Illustration of prediction fairness. Each cell represents the algorithmic bias against a historically disadvantaged student subpopulation (compared to the corresponding reference group) in the specific scenario. Crosses represent statistically significant biases ($p < 0.05$) after correcting for multiple testing. Short-term success: whether a student’s final course grade was above the class median. Long-term success: whether a student’s average GPA in the following academic year was above the class median.

assessment of socio-emotional skills were least predictive of course success, which is similar to the ineffectiveness of our survey data. On the other hand, they found that models using institutional variables and clickstream features performed better and comparably to one another, as we did. They also discovered that combining clickstream behaviors with socio-emotional skills outperformed institutional data alone, which we also saw with the FNR for the long-term outcome. Interestingly, they did not find additional predictive utility of higher-level behaviors (sequential features) from clickstream data, which we did not further investigate.

The limited ability of pre-course survey data to accurately predict either short-term or long-term success may suggest that self-reported measures of self-regulated learning are not key factors of online learning processes or performance. However, as suggested by previous research [12], it may also suggest that students tend to overestimate their use of learning strategies in online courses. This is likely because students make estimations of their future behaviors based on memories of similar past events that are usually unreliable [21].

Thus, more research is needed to understand how to help students provide valid data of their learning skills as well as other psychological attributes in surveys [25].

When it comes to fairness, several interesting trends emerge. First, predictions using institutional data, which had the lowest FNR overall, were actually discriminatory when it comes to FNR for both outcomes. In particular, institutional data discriminated against students from underrepresented minority groups, low-income students, first-generation college students, and students with low high school GPA. This suggests that these models tend to disproportionately label students from these subpopulations as having below-median performance. In order to achieve higher overall accuracy, these models appear to be using a heuristic of classifying students as above or below median based on the majority class within the subpopulations that they belong to (see Figure 1). Therefore, one of the main sources of unfairness may just be the original class imbalance in different student subpopulations. When this imbalance results from historical inequities, the model will simply replicate those

inequities and produce unfair predictions.

On the other hand, we found that using click features tended to be fair with respect to FNR, but instead somewhat discriminatory with respect to FPR, for several student subpopulations. Contrary to the discrimination brought by institutional features, this form of discrimination could occur just because the model is blind to individual background. More specifically, students coming from different backgrounds may on average exhibit similar learning behaviors, but their likelihood to succeed might differ due to factors that correlate with their socio-economic status. Since the click features do not have access to students' background information, they may predict that students from disadvantaged backgrounds are likely to succeed at a disproportionately high rate.

One specific and possibly counterintuitive trend is seen when it comes to gender biases. While none of the feature sets discriminated against female students in terms of FNR, almost all of the feature sets discriminated against them in terms of FPR for at least one of the two outcomes. In fact, female students tend to have higher GPA than their male peers in the dataset (see Figure 1). This reinforces the inference that for institutional features, the models classify students into the majority class of their subpopulations in order to maximize accuracy. On the other hand, the fact that using only LMS and/or survey data is also biased against female students in terms of FPR might be due to something else. This suggests that female students might (a) exhibit different click behaviors and survey responses from men, which tend to be predictive of better performance; or (b) have different baseline levels of engagement (e.g., likelihood of clicking on LMS pages) independent of their likelihood of success. If the former is true, click behaviors and/or survey responses could act as a weak proxy for gender, even though gender is not encoded in these features.

5.2 Practical Implications

In general, prediction errors are inevitable, but it is important to be aware of and minimize potential misplacement that may result in severe negative consequences. Below, we discuss three major scenarios where prediction models are used for educational decision making and the implications of our findings in these cases.

First, higher education has a long history of screening applicants for desirable educational opportunities such as merit-based scholarships, where the award is based on the prediction of student future performance. In this case, underestimating student performance may limit their educational development. While institutional data is one of the most widely used data sources for these purposes, our results suggest that institutional data alone might be more likely to underestimate achievement of students from disadvantaged background as compared to their peers. Moreover, these systematic biases do not go away easily even when other common data sources are added. Therefore, it is important for policymakers to cautiously employ predictive analytics for selecting students since it may result in unfair exclusion of already disadvantaged students from critical educational opportunities and access to social mobility through education [18].

In community college settings, institutional data has also been used to evaluate students' readiness for college-level courses and assign students into remediation [32], as well as to understand the impact of remedial and preparatory courses on subsequent college success [24]. Put in this scenario, our results would suggest that students from historically disadvantaged subpopulations are more likely to be misplaced into remediation than their counterparts when they are actually capable of taking advanced courses. While remedial courses are designed to help academically underprepared students, they also increase students' cost and may delay student progression towards their degree goal [4]. For both this and the previous application scenarios, a potential algorithmic solution might be setting separate thresholds for different subpopulations to ensure fairness, as [20] suggested.

Finally, in the recent research and practice of online learning, LMS data have been commonly used to predict student performance and identify at-risk students [36]. Students who are identified as being at risk of low performance or dropout will often be placed into light-touch or optional academic support, such as receiving email reminders and tutoring services [11]. In this context, it might be more concerning to overestimate student performance and ignore students in need than to underestimate student performance and place them to educational resources that they could opt out of. Our findings indicate that compared to males, female students would be especially likely to experience overestimation and therefore would not receive academic resources that they need. In this case, incorporating institutional data into the prediction might not be as problematic in order to leave no student behind.

6. CONCLUSION

In this paper, we responded to the call for research to evaluate and compare the utility of common student data sources (i.e., institutional data, LMS data and survey data) for building predictive analytics applications in the context of higher education [14]. We aimed to find out what data sources and their combinations predicted short-term and long-term college success both accurately and fairly across different student subpopulations. Our results suggest that overall, institutional data and LMS data on their own have decent predictive utility for either instructors' or policymakers' needs to identify students in need. Using them together further strengthens that predictive power. Survey data alone poorly predicts student success and only marginally helps alleviate some of the prediction errors in the presence of other data sources. With regard to fairness, institutional data consistently leads to higher false negative rate (underestimation) within historically disadvantaged students subpopulations than within their peers. LMS data, on the other hand, tends to overestimate some of these disadvantaged groups (e.g., female students) more often than their counterparts and these biases would be overridden by institutional data when the latter is added. Survey data makes very limited contribution to fair predictions. Interestingly, all sources of student data tend to overestimate female students who perform better than male students on average in our case. Also, students with lower prior achievement are no less affected by underestimation than underrepresented demographic groups.

These results combined suggest that using multiple data

sources in college success prediction is beneficial for institutional stakeholders from both technical and ethical perspectives. Specifically, given the infancy and decent predictive utility of LMS data, institutions should feel encouraged to invest in the infrastructure to store, manage and analyze such data and integrate LMS-based behavioral measures into the routines of institutional research. On the other hand, utilizing multiple data sources still cannot guarantee fair predictions of college success especially for students who have less competitive academic records and who are historically disadvantaged in higher education. Therefore, it is advisable to combine the intelligence of experienced practitioners and data-driven applications for decision-making in the wild, in hopes of minimizing the risk that students are unfairly excluded from their optimal pathways due to biased algorithms or human judgement.

Our work has a few limitations which point to meaningful future work. First, the scope of our feature sets was limited and not representative of the full potential of different data sources. For example, for survey features we only used measures of self-regulation, but there are other psychological constructs that play equally important roles in learning processes. Therefore, our findings should be taken as a proof of concept in terms of systematically evaluating different data sources. Future work will extend the current piece to more comprehensive data sources that institutions have good control over [19, 3] and to broader feature sets informed by existing research. Second, while we briefly reflected on the prediction results and practical implications, we did not formally examine how the biases illustrated in Figure 2 permeate through the predictive analytics pipeline. Future work will examine this aspect more thoroughly, as well as how to convey these sources of bias to stakeholders for more prudent decision-making on student data usage.

ABSTRACT

The *2nd Annual WPI-UMASS-UPENN EDM Data Mining Challenge* required contestants to predict efficient test-taking based on log data. In this paper, we describe our theory-driven and psychometric modeling approach. For feature engineering, we employed the Log-Normal Response Time Model for estimating latent person speed, and the Generalized Partial Credit Model for estimating latent person ability. Additionally, we adopted an n -gram feature approach for event sequences. For training a multi-label classifier, we distinguished inefficient test takers who were going too fast and those who were going too slow, instead of using the provided binary target label. Our best-performing ensemble classifier comprised three sets of low-dimensional classifiers, dominated by test-taker speed. While our classifier reached moderate performance, relative to competition leaderboard, our approach makes two important contributions. First, we show how explainable classifiers could provide meaningful predictions if results can be contextualized to test administrators who wish to intervene or take action. Second, our re-engineering of test scores enabled us to incorporate person ability into the estimation. However, ability was hardly predictive of efficient behavior, leading to the conclusion that the target label's validity needs to be questioned. The paper concludes with tools that are helpful for substantively meaningful log data mining.

1. INTRODUCTION

With the *2nd Annual WPI-UMASS-UPENN EDM Data Mining Challenge*,¹ the organizing consortium continued a young series of data competitions featured by the Educational Data Mining Society. The data challenge consisted in predicting students' behavior in a second test part using the log data produced in a first test part. The organizer's goal was to identify students who will act inefficiently by rushing through the second test half or not reaching the end of the test [19]. Another central, and noticeably constraining, secondary goal was that accurate classification should be reached as early as possible during test administration (i.e., with as little log data as possible) [19].

In this paper, we report details on our theory-driven psychometric contribution to the competition.² Opposed to data-driven analyses, a theory-driven one is characterized by identifying potential mechanisms at play and an according selection of methods, features, or both. The focus on a theory-driven feature-engineering access rather than some presumably more powerful deep-learning or other black-box methodology traces back to our team's psychometric background with strong experience in log data analysis. We believe that the theoretical understanding of underlying behavioral and cognitive processes that drive characteristics of test-taking behavior such as efficiency is crucial for build-

²Our competition contributions have been submitted under the name *Team TBA* (Centre for Technology-Based Assessment | DIPF).

ing predictive models as requested in the given competition. Otherwise, the risk of integrating spurious associations into productive classifiers is high. Moreover, in the present paper, we provide evidence that the validity of the data challenge’s target label needs to be reassessed since we could show that students’ ability was hardly associated to the target label. Ability estimation was enabled by the re-engineering of scores from the log data—a unique contribution of the present paper. We suggest potential solutions for identified issues.

Efficiency can be defined as the characteristic of producing desired results without waste [13]. In the context of efficient test taking, this corresponds to successful test taking with minimum effort or time. Obviously, efficiency involves two components, namely goal-reaching and resource-saving. As we elaborate on in detail throughout the following sections, the competition’s operationalization of efficiency strongly emphasizes the latter component, but largely neglects the former. This consideration is emblematic and shows the value of a theory-driven and psychometric access to the matter. We regard log data that is captured during test administration as process data, which means it constitutes “empirical information about the cognitive (as well as meta-cognitive, motivational, and affective) states and related behavior that mediate the effect of the measured construct(s) on the task product” [7]. Thus, log data from assessment contexts is not just a by-product which is nice to have, but it carries relevant information and can be drawn on for purposes such as the one promoted in the competition.

With respect to classification performance, our competition contribution ended up in the top quarter of leaderboard submissions and was ranked eighth within the teams that submitted their code in time [20].

The paper first describes the setup provided by the competition organizers, then focuses on our approach for feature engineering as well as classifier training, and closes with reporting and discussing results on the classifier’s performance level as well as single features’ predictivity. The Conclusion Section elaborates on the definition of efficient test taking and discusses the state of the art for corresponding operationalizations. Please note that we use the terms *task* and *item* interchangeably here, in accordance with each community’s practice.

2. COMPETITION SETUP

2.1 Data

The competition data set [19] comes from the National Assessment of Educational Progress (NAEP), which is a US national assessment conducted across 4th-, 8th-, and 12th-grade students, including tests on a variety of subjects every two years. Specifically, the data set provided for analysis within the competition comes from the 2017 test for 8th-grade students in mathematics. The test comprised two test blocks (Block A and B) that were time limited to 30 min per block.

The NAEP 2017 mathematics assessment was digitally administered on tablet computers with keyboards [15]. The test items covered several domains such as algebra or geometry and were either presented as pure mathematics tasks or

as tasks applied in an everyday context. The items included stimulus material (text and/or figures) and either a list of responses to choose from (multiple choice), drag and drop response elements, or one or more text fields for constructed responses. The students were able to navigate between items within the same test block. For some items, a virtual calculator was available. The test environment also included a virtual drawing tool, which allowed students to freely draw and make handwritten annotations, a text-to-speech feature, which could be used to listen to the tasks’ written materials, and a help button offering the students information about the handling of the test environment. Before the first item, a screen with general instructions was presented, called *directions*. After the last item, a review screen was presented indicating the end of the test block. The students could navigate from the review screen back to the items and onward to the next test block. Students’ actions in this virtual environment (i.e., clicking on elements or keystrokes when typing a response) were recorded as log data events. The data provided 42 different events (e.g., **Enter Item**, **Click Choice**, **Back**). From this log data, it is possible to reconstruct the course of each student’s test completion behavior.

For the competition, the organizers arranged the log data into two sets. The first one was a training set, taken from Block A with log data for $n_{train} = 1232$ students across the whole 30 min of Block A. The data set was accompanied by the target label indicating whether students behaved efficiently in Block B (see next section). The second data set was an evaluation set for which efficiency labels had to be predicted by the contestants. This evaluation set comprised log data stratified into three conditions: i) $n_{10min} = 411$ students with 10 min of log data from the start of Block A; ii) $n_{20min} = 411$ students with 20 min of log data from the start of Block A; iii) $n_{30min} = 410$ students with complete 30 min of Block A. The competition organizers halved the evaluation set so that the leaderboard displayed the teams’ prediction accuracy on one half of the evaluation set, and the final evaluation was carried out on the remaining half. The training and evaluation sets consisted of 438,291 and 301,924 event logs, respectively.

2.2 Target Label: Efficiency

The competition organizers categorized the students into two groups. The value **True** indicated that a student completed Block B efficiently, while **False** indicated inefficient student test-taking behavior in Block B. Students were labeled efficient when they met two criteria: “1) being able to complete all problems in Block B, and 2) being able to allocate a reasonable amount of time to solve each problem” [19].

The definition of efficiency captures two key test-taking behaviors: students who go too slow, and as such fail to complete all the items in a block, and students who go too fast through the test, therefore not spending enough time on each question. Students who are inefficient through being too slow can easily be identified due to their failure to complete all tasks. However, for students going too fast, “a reasonable amount of time” can be difficult to operationalize. As such, the organizers chose to impose an arbitrary threshold for which students were evaluated on the total time taken on a task, with “the 5th percentile as the cut-off for the

‘reasonable amount of time’ [19]. This operationalization led to labeling 39.6% of the students in the training data as inefficient.

2.3 Evaluation Metrics

The objective of the competition was to develop a classifier model that would predict student efficiency. The prediction was evaluated against two key measures, the adjusted AUC and an adjusted kappa. The AUC stands for Area Under the Curve and comes from ROC analysis [4]. It compares the false positive rate to the true positive rate of the model, measuring how well the model predicts the correct outcome versus an incorrect prediction. A value of $AUC \leq .5$ would indicate a model performing no better than random chance. As such, the competition used an adjusted AUC measure, $AUC_{adj} = (AUC - 0.5) * 2$.

The second measure, kappa, also captures classifier performance by comparing how much two raters agree in classifying a given set of data beyond chance. Conceptualized by Cohen [3], it compares the observed accuracy to the expected accuracy between two classifiers. As such, the value of kappa needs to be above zero to indicate performance above random chance. The competition utilized an adjusted kappa value, κ_{adj} , in that they set the lower limit of kappa to 0. For the evaluation of the models within the competition, an aggregated score was made from AUC_{adj} and κ_{adj} .

3. METHODS

In this section, we first describe a data transformation step of splitting the three temporal conditions for feature extraction and training. This turned out to be essential for achieving appropriate classifier generalizability to the test set. Next, we describe our feature engineering as well as restrictive feature selection, and we close the section with outlining how the strings were pulled together for building an ensemble classifier for prediction.

All statistical analyses have been carried out using *R 3.6.1* [16], with the package *mlr 2.17.0* [2] for machine learning, *TAM 3.3-10* [18] for item difficulty and person ability estimation, and *LNIRT 0.4.0* [6] for item time intensity and person speed estimation.

3.1 Improving Generalizability by Separating Conditions

Our early submissions of predictions to the leaderboard revealed that the classifiers’ performance—though evaluated by stratified, repeated cross-fold validation—would always decrease substantially when being evaluated on the test set. That is, the generalizability of these classifiers to the test set was low, even when cross-validations testified to stable out-of-sample classification.

The primary reason that we identified was that the training set contained 30 min of log data, whereas the test set was split into three conditions with only the first 10 min, 20 min, or the full 30 min of log data available (see Section 2.1). Obviously, it is reasonable that feature realizations and their indication for one class vary over (testing) time. As an example, the time students take to work on single tasks does not only vary by task characteristics, but is also

influenced by the task’s position within the test. Another example is the log event of the timeout screen that limits students’ time to 30 min. Naturally, this event is reasonably predictive, but while it is available in the 30 min condition, it is not in the 10 min or 20 min condition. Therefore, training sets for each condition were necessary for the classifiers to generalize more properly to the test set.

For this purpose, we created three data sets: (i) the first 10 min of log data from the 10, 20, and 30 min conditions for predicting test set cases with 10 min of log data, (ii) the first 20 min of log data from the 20 and 30 min conditions for test-set cases with 20 min of log data, and (iii) the full 30 min of log data for test-set cases with 30 min of log data. For feature extraction, we combined the respective training and test (sub)sets. This way, we maximized the available information for norm-referenced features and parameter estimation procedures. Since we employed supervised learning methods, the test sets were excluded from classifier training.

The result of splitting the conditions was that we constructed three classifiers for each learning method and set of features. Each case in the test set, however, was classified by only one model, determined by the condition the test case belonged to.

3.2 Feature Engineering

In this section, we describe the selection of engineered features of which some ended up in at least one of the base classifiers that formed the final ensemble bag. We start with the two crucial psychometric models used for estimating students’ speed and ability. Then we describe our approach of extracting features from log data and deriving simple indicators that we assumed would indicate efficient or inefficient test behavior, using the software package *LogFSM*. Finally, we describe the concept and operationalization of rapid guessing as well as an adopted technique for representing log event sequences.

3.2.1 Latent Test-Taker Speed

Efficient test taking as operationalized in the competition (see Section 2.2) is mainly characterized by test takers’ time handling. If a student went relatively quickly through the test (in Block B), they were labeled as inefficient. If a student spent too much time on some tasks (in Block B), they would not be able to complete all tasks and thus be labeled as inefficient, too. Therefore, the most evident feature is test-taker speed.

Test-taker speed can be inferred from the time spent on tasks in a test. However, the time spent on a task is determined by the characteristics of the task and the test-taker. On the one hand, task characteristics, such as complexity, require and evoke a shorter or longer time on task due to the task’s inherent *time intensity*. On the other hand, some test takers will have the tendency or skill to move faster through a test than others; this characteristic is called *test-taker speed*. Both time intensity and test-taker speed are not directly observable and can only be estimated as latent variables.

A model that allows the separation of time on task into item and person parameters is the *Lognormal Response Time*

Model [22]:

$$f(t_{ip}; \tau_p, \alpha_i, \beta_i) = \frac{\alpha_i}{t_{ip} \sqrt{2\pi}} \exp \left\{ -\frac{1}{2} [\alpha_i (\ln t_{ip} - (\beta_i - \tau_p))]^2 \right\} \quad (1)$$

Response time distributions take values in the positive reals and typically have long tails. The log-transformation hence is a sensible way to approximate normality and is expected to lead to better fit than a normal model on the raw response times [22]. The lognormal model takes three parameters into account and is based on the log-transformed time t_{ip} that person p spent at item i . Item time intensity β_i captures item i 's tendency to evoke more or less time spent for completing it. Test-taker speed τ_p is a person's tendency and ability to spend more or less time on item completion. Because some items will show more homogeneous time distributions than others, the dispersion parameter α_i estimates an item's discriminatory power.

The parameters of interest are estimated in a Bayesian framework using a Markov Chain Monte Carlo method with a Gibbs sampler [22, 6]. We used expected a posteriori (EAP) estimators of test-taker speed τ_p as features for predictive modeling.

3.2.2 Latent Test-Taker Ability

The provided log data did not include task scores, so scores were re-engineered based on the log data and information from released items available through the NAEP questions tool [5]. To do this, unique item identifiers were mapped to example items provided in the NAEP questions tool, a public query tool used to showcase NAEP questions. The mapping was verified by text-to-speech contents in the log data. From this, the correct responses to items could be coded for 14 of the 19 items included in the competition data set. Using the 14 scored items, we estimated an intermediate ability score for test takers. By identifying the top 100 test takers across the 14 items, we then used their responses to the remaining 5 unreleased items to identify the most likely correct answer, thus inferring the correct scoring for the data. With this complete set of scores, we applied a Generalized Partial Credit Model [14] for estimating person ability. Theoretically, such ability estimates together with the speed estimates should be reasonably predictive of efficiency as efficiency is defined by a trade-off between performance and effort (see Section 1). The model is represented by the following equation [14]:

$$P_{jk|k-1,k}(\theta_p) = \frac{\exp[a_j(\theta_p - b_{jk})]}{1 + \exp[a_j(\theta_p - b_{jk})]} \quad (2)$$

The equation models the probability of a person p with the latent ability θ_p to respond to an item j by choosing the k th response category. In this model, subsequent response categories are ordered by their difficulty. The parameter b_{jk} represents the difficulty of an item's response category and a_j constitutes the item discrimination (i.e., the degree to which the item is capable of distinguishing between more or less able test takers). We used Marginal Maximum Likelihood for estimating model parameters. For person ability, Weighted Likelihood Estimators [24] were used. This way, test-taker ability θ_p can be directly used as a feature for

predictive modeling.

3.2.3 Simple Indicators of Students' Work Process

The analysis of process indicators is based on the assumption that latent characteristics of a test taker can be inferred from attributes of their work process [7]. However, the creation of indicators is often retrospective, depends on the specific assessment system employed, and is based on plausibility and expert opinion about which indicators might be of potential interest for a particular research question (e.g., time on task, number of page visits, or switching between environments). With the intent to provide a tool to facilitate the creation of process indicators from log data, the software package LogFSM [9] has been developed that can be used in R. Instead of providing a list of generic indicators, LogFSM requires the formulation of one or multiple theoretical models that a test developer or researcher has about the work process in a task. Afterwards, LogFSM reconstructs a given set of log data according to the predefined theoretical model(s). Attributes of the reconstructed work process then serve as process indicators.

The procedure of LogFSM utilizes the concept of finite state machines [10]. The work process is decomposed into a finite number of states which represent sections of the theoretically defined response process. For example, a researcher who wishes to distinguish process components in a math assignment might define the states *Task Reading*, *Task Processing*, *Responding*, and *Reviewing* that could alternatively be collapsed into states of lower granularity like *Stimulus Processing* and *Task Answering*. Practically, states are identified by events that represent test-taker interactions with the assessment platform (i.e., log events). The occurrence of such events can serve as the conditions that must be met in order to change from one state to another one, which is called transition. The interpretation of an event might differ from state to state, which may result in differences as to whether or not a transition is triggered. Depending on the previous state of a test taker, for example, a radio button click event might be interpreted as a first-time response (*Responding*) or an edited response (*Reviewing*). In summary, the interpretation of states and state sequences is constituted by the interplay of visible components of the assessment system (e.g., texts, images), the possibilities for interactions (e.g., buttons, text fields), the contexts in which events take place (e.g., accessing a calculator before or after a response was given), and—most importantly—the predefined assumptions about test-taking behavior and cognitive operations (e.g., reading instructions, reconsidering an answer) [10].

Finally, process indicators can be derived as attributes of the reconstructed states (or the reconstructed sequence of states) from log data that contextualize test-taking behavior according to the theoretically assumed test-taking process. The integration of the characteristics of a task, the available log events, and the theoretical expectations about the test-taking behavior assign a substantive meaning to an indicator [10]. For example, an indicator that reflects how long a student actually spends reviewing and checking a particular response again can be defined as the total time in a state *Reviewing* aggregated over multiple revisits of the task and cleaned for the time in other states such as *Responding*.

For the competition’s data analysis, we specified five FSMs to represent different attributes of students’ work process. The states of these FSMs represented students’ on-screen page (26 states); attempting, processing or reviewing of one of the 14 multiple-choice tasks (46 states) and tasks with other response formats (19 states); students’ use of the text-to-speech tool (4 states); and their use of the calculator and the drawing tool (5 states). Figure 1 shows the last mentioned model as an example. We distinguished between having the calculator active (state *CalcOn*), having the drawing tool active (state *textit*), and both tools being inactive (state *textit*). Transitions between states were triggered by the log events described in Section 2.1. For example, the state *CalcOn* was transferred to the state *ToolsOff* when the calculator was closed. That is, when the student pressed the calculator button (*CloseCalculator*), the drawing tool was activated (*ScratchworkModeOn*), or the item was left (*ExitItem*). Vice versa, when the drawing tool was activated, students’ could not open the calculator, allowing for the modeling of distinct states. Self-transitions were specified to deal with, for example, double-clicks.

Several simple indicators were then derived as aggregated attributes of the reconstructed states or sequence of states. For example, the number of occurrences of the state *CalcOn* across items reflects how often a student opened the calculator during the assessment. A summary of the derived simple indicators and their descriptions is provided in Table 1.

3.2.4 Rapid Guessing

Compromised effort and persistence have been shown to be identifiable by investigating rapid guessing behavior [25]. The concept of *rapid guessing behavior* is based on the assumption that the amount of time that a test taker spends on a task before responding is not sufficient to perceive the task and develop a serious solution [21]. A rapid guess is therefore defined as a response to a task with a response time below a certain threshold.

For the definition of the thresholds, multiple approaches are possible [26]. Following the competition’s operationalization of inefficient test-taking behavior [19], the present work identified task-specific response time thresholds for rapid guesses based on a 5th percentile cut-off value. This implies the assumption that the slowest 5 percent of test takers on each item showed rapid guessing behavior. This was in line with the competition’s definition of inefficient test-taking behavior and, thus, necessary for predicting the accordingly constructed target label. However, this is not state of the art and the Discussion Section reviews alternative approaches.

On the basis of the identified rapid guesses, a response matrix X_{pj} was constructed, indicating whether a response to task j by person p was observed and identified as a rapid guess. The entries in this matrix are specified as follows:

$$x_{pj} = \begin{cases} \text{NA} & \text{if no response is observed} \\ 0 & \text{if a response is observed \& a rapid guess} \\ 1 & \text{if a response is observed \& no rapid guess} \end{cases} \quad (3)$$

X_{pj} was then used to extract several rapid guessing indicators. The indicators encompass a dichotomous grouping-

Table 1: Simple Indicators Serving as Features or Used for Derived Feature Modeling

Indicator	Description
Time on Screen	Time a student spent on each task within the test. This included the directions, review, and help screens.
Tasks Attempted	A count of the number of tasks at which a student showed behavior indicating they were attempting to complete the task.
Tasks Completed	A count of the number of tasks a student had completed such that it could be scored.
Tasks Incomplete	A count of the number of tasks which a student attempted, yet left the response area with incomplete information; e.g., only placing 3 out of 4 drag-and-drop boxes into the response area.
Timeout	A binary variable indicating whether a student received the time-out screen, typically indicating that they failed to complete all tasks within the time limit of 30 min.
Reviews	A count variable indicating the number of times a student visited the review screen.
Too Fast	A count variable indicating the number of times a student was in the fastest 5% of test respondents for a given task.
Viewed/No Attempt	A count variable for the number of times a student viewed an item without interacting with the item in any meaningful manner.
Time on Directions	A time variable capturing the total amount of time spent on the directions screen.
Text to Speech	A count variable indicating the number of times a student utilized the text-to-speech feature.
Help	A count variable for the number of times a student opened the help dialogue to seek assistance.
Calculator	A count variable for the number of times a student opened the calculator feature.
Drawing Tool	A count variable for the number of times a student opened the drawing tool.

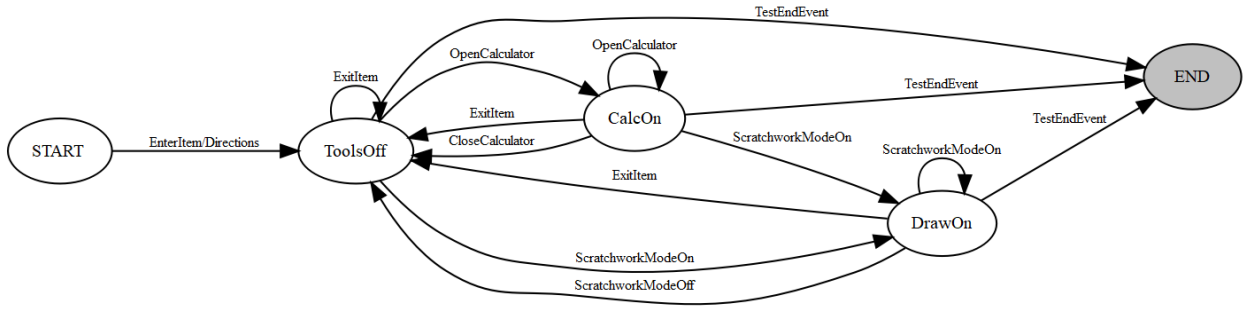

Figure 1: Exemplary Finite State Machine for Reconstructing Information from the NAEP Log Data

variable (whether a person showed at least one rapid guess), the sum of rapid guesses, and an estimation of a latent rapid guessing propensity [11]. For the estimation of the latent rapid guessing propensity, a Rasch model [17] was selected:

$$P(X_{pj} = 1) = \frac{\exp(\theta_p - \sigma_j)}{1 + \exp(\theta_p - \sigma_j)} \quad (4)$$

The Rasch model is similar to the GPCM presented in Section 3.2.2, just reduced to the dichotomous case and keeping the discrimination parameter constant. While the notation of symbols and indices is generally continued here, σ_j represents an item's difficulty (or propensity to evoke rapid guessing) and X_{pj} denotes the observed response correctness (or rapid guessing behavior), with $x \in \{0, 1\}$. For person parameter estimation, Expected A Posteriori estimates were used.

3.2.5 *n*-Grams of Log Events

The occurrence of certain log events can indicate behaviors or unobservable meta-cognitive, cognitive, or affective states of interest. This is also true for combinations of such. In the context of the competition, disengaged behavior might be a precursor or indicator for (later) inefficient test taking. For example, (a) whether a student uses the assessment system's drawing tool in a task that does not require its usage could be indicative of inefficient test taking as could be (b) the playing-around with the text-to-speech feature. For incorporating such predictive features, we adopted an approach by He and von Davier [8] that borrows techniques from natural language processing and information retrieval.

At the core of the procedure [8], a student's log events are considered as *n*-grams of a sequence. *n*-grams constitute all possible tuples of subsequent log events within a student's complete sequence of log events. For computational as well as sample size reasons, it is common to limit analyses to uni-, bi-, and trigrams. Hence, a sequence such as ACAD (representing four log events) would be decomposed into four unigrams ($2 \times \langle A \rangle$, $\langle C \rangle$, $\langle D \rangle$), three bigrams ($\langle AC \rangle$, $\langle CA \rangle$, $\langle AD \rangle$), and two trigrams ($\langle ACA \rangle$, $\langle CAD \rangle$). We decided to make each event task-specific; that is, the event **Draw** was captured together with the task ID, for example, **DrawTask4**. This way, events were contextualized. Varying by the 10, 20, and 30 min conditions, we obtained 7448, 13,482, and 17,553 *n*-grams, excluding sequences that occurred in less than 15 students' sequences.

Next, the frequency sf_{ij} of each *n*-gram *i* is computed for each student *j* (i.e., sequence frequency). These frequencies are then weighted by inverse sequence frequency (borrowing from the term *inverse document frequency*), $ISF_i = \log(N/sf_i)$, with *N* representing the total number of sequences, and log-normalized; that is $(1 + \log(sf_{ij})) * ISF_i$. This way, sequences occurring across many test administrations are scaled down in their importance and vice versa. Also, higher frequencies are dampened by the log-transformation.

The weighted *n*-gram frequencies can then be checked for their predictivity of, for example, efficiency, using a χ^2 -distributed statistic (details at [8, 12]). This revealed 841, 1259, and 1190 significantly predictive *n*-grams ($\alpha = .05$) for the respective condition.

In a last step, we compressed the selected features in a principal component analysis. Due to the need for a low-dimensional feature space (see Section 3.3), we extracted only a few components, retaining only 5% of the original information. This resulted in 6, 9, and 14 components, respectively, for the three conditions.

3.3 Feature Selection

We applied several different feature selection strategies. First, we used random forests to obtain features' importance for predicting students' efficiency in Block B. Second, we evaluated the accuracy of predictions using different combinations of features. Both strategies showed speed to be the most predictive feature in all conditions. However, the importance of the other features differed depending on the data set and combination of features.

Moreover, we frequently observed that if the addition of a feature improved the classification performance on the training data substantially (evaluated by stratified, repeated ten-fold cross-validation), it reduced the performance on the test data significantly. Thus, low-dimensional models were always to be favored over high-dimensional ones. For our final ensemble bag, the 10 and 20 min classifiers indeed turned out—with one exception—to work best with only one single feature: latent person speed. In the 30 min condition, more features were selected for the final prediction. For a list of the resulting features for all conditions, see the following Section 3.4.2.

Table 2: Three Sets of Base Classifiers

<i>Classifier Set (1): Speed & Test Completion</i>						
	ML	Speed	#Complete	#Incomplete	#TooFast	n-grams
10min	SVM	+				
20min	SVM	+	+			
30min	SVM	+	+	+	+	
<i>Classifier Set (2): Multiclass Speed & Test Completion</i>						
	ML	Speed	#Complete	#Incomplete	#TooFast	n-grams
10min	mSVM	+				
20min	mSVM	+				
30min	mSVM	+	+	+	+	
<i>Classifier Set (3): Speed, Test Completion, & n-Grams</i>						
	ML	Speed	#Complete	#Incomplete	#TooFast	n-grams
10min	JRip	+				+
20min	SVM	+				+
30min	SVM	+	+	+	+	+

3.4 Prediction

3.4.1 Harvesting More Information: Multi-Label Classification

The binary target label split students into efficient and inefficient test takers. However, the competition’s definition of *inefficient* behavior mixed two types of test takers: those who are going too fast and those who are going too slow. Since the two types have different feature realizations, the learning algorithms have to optimize towards at least two different conditions for the same class. Most algorithms’ optimization works better if they have less conditions to optimize for within each class.

Therefore, we used the latent test-taker speed feature for further splitting the inefficient category into *Going Too Slow* and *Going Too Fast*. This new target label with now three instead of two classes was used for one set of classifiers (see Section 3.4.2). For doing so, the latent speed estimated by the Lognormal Response Time Model (see Section 3.2.1) distinguished between students going too fast and going too slow. An analysis showed that substantial rapid guessing behavior started at a threshold of about $\tau = 0$ and, thus, optimally divided the two inefficient groups. The resulting target label identified about 23% of the test takers as going too fast and about 17% as going too slow, keeping the original share of 60% of efficient test takers.

3.4.2 Three Sets of Base Classifiers

For the final prediction, we created three sets of base classifiers that were to be merged in an ensemble bag. Each set followed a different idea, incorporated different features, and was trained by a different learning algorithm. In turn, each set contained three classifiers, with one of them tailored to the 10, 20, and 30 min condition, respectively. We experimented with different feature sets, learning algorithms (common ones such as support vector machines, AdaBoost, J48, neural nets, and others), and hyperparameters for each base classifier. Table 2 shows which features and learning algorithms were used in which classifier. Which features were included and which learning algorithm was employed was determined by resulting performance with respect to the leaderboard. Due to the unstable performance in the test set, no systematic hyperparameter tuning was carried out.

Our first set of classifiers used support-vector machines with a radial kernel and C-classification for all three conditions

(with $C = 1$, $\gamma = 1/n$, $\epsilon = 0.001$, shrinking). In the 10 min condition, only speed was used for the prediction. In the 20 min condition, the number of completed items was added. In the 30 min condition, all features that got through feature selection (except n-grams, on purpose) were incorporated: speed, number of completed items, number of incomplete items, and items completed too fast.

Our second set of classifiers was designed similarly to the first one, but with a multiclass support-vector machine and the multiclass label distinguishing going-too-slow and going-too-fast students (see Section 3.4.1). In the 10 and 20 min conditions, speed was the only predictor of importance according to the feature selection procedure. In the 30 min condition, again, all features (except n-grams) were incorporated.

Our third set of classifiers differed from the other two sets in that it incorporated one principal component of the n-grams of event sequences (see Section 3.2.5). Apart from that, the same set of features were used like in the second classifier set. The 10 min condition made use of a propositional rule learner instead of the otherwise employed support-vector machine. The rule learner’s parameters were set to $F = 3$ folds, $N = 2$ as the minimal weight, maximum error rate of included rules $\geq .5$, and pruning was used.

3.4.3 Ensemble Bag

The three described sets of classifiers were combined in a final ensemble classifier. We used the bagging approach by averaging probabilities of a condition’s three base classifiers, but favoring inefficient classifications. We chose to favor inefficient classification since our base classifiers produced not enough inefficient classifications. Therefore, we ended up with one ensemble bag of classifiers for the 10, 20, and 30 min condition each.

4. RESULTS

The final evaluation of our prediction resulted in $AUC_{adj} = 0.27$ and $\kappa_{adj} = .19$. In the leaderboard with all 82 competitors, this corresponded to rank 25, with several teams having submitted multiple results. In the final table, which only included 13 teams that submitted their code in time, our contribution was ranked eighth. The winner achieved $AUC_{adj} = 0.34$ and $\kappa_{adj} = .22$. The rather low performance values, even for the winners, were accompanied with corresponding differences between the test and evaluation set, resulting in substantial changes in the ranking and indicating rather unstable models being prone to changes in the evaluation data. This is in line with the wavering performance during testing we observed.

With respect to single features, two of them draw particular interest: test-taker speed and ability. Figure 2 shows their ROC curves. Obviously, the latent speed feature taken alone predicts efficient test taking noticeably well ($AUC_{adj} = 0.36$, $\kappa = .30$ in a single-feature support-vector machine³). In contrast, students’ ability does not capture a lot of relevant information for predicting efficient test taking ($AUC_{adj} = 0.16$, $\kappa = .07$ in a single-feature support-vector machine³).

³based on the 30 min training data and a stratified 10-times tenfold cross-validation

Figure 2: ROC Curves of Two Features: Speed (left) and Ability (right)

The large overlap of distributions between efficient and inefficient test takers for the ability feature further shows that the efficiency label does not contain much information about test takers’ ability (right part of Figure 3). There is a small difference in that inefficient students have lower ability values on average ($\Delta = -0.08$, Cohen’s $d = -0.20$). While the overlap of distributions appears somewhat similar for the speed feature (left part of Figure 3), the long right tail and prominence of faster inefficient test takers makes the feature space more easily separable. The effect size of the subgroups’ difference is remarkably higher ($\Delta = 0.12$, Cohen’s $d = 0.57$).

Finally, the feature space which is formed by ability and speed is plotted in Figure 4. The large majority of test takers builds an indistinguishable cloud. The other main message of this plot is, first, that very fast and less able test takers were consequently classified as inefficient in Block B. More surprisingly, second, a few test takers who were relatively fast, but answered correctly (and were thus estimated as relatively able) were classified as *inefficient* in Block B. It is possible that these students changed their behavior in the second test block. The other possibility is that the efficiency label classifies these instances erroneously as inefficient.

5. DISCUSSION

In this paper, we present a theory-driven psychometric modeling approach to predicting efficient test taking behavior in the context of the NAEP Data Mining Competition for 2019. The paper makes two important contributions, one to our understanding of the data, another to the structure of the competition.

The first major contribution is the value of theory-driven psychometric modeling for feature engineering. Referring back to Merriam Webster’s bipartite definition of efficiency as the characteristic of producing desired results without waste [13], it is interesting how task success is not incorporated into the competition’s conceptual specification of test takers. The data patterns mirror the lack of the desired results in the competition’s operationalization of the target label, demonstrating the prominence of speed as the sole determinant for the classification as efficient test taking. Remarkably, the outstanding speed feature serves as the only feature in some classifiers of our final ensemble bag that only

falls short of the winning contribution by $\Delta AUC_{adj} = .07$ and $\Delta \kappa = .03$. Empirically, ability did not provide any incremental increase in kappa or AUC beyond the speed feature. As a result, the ability feature was not included in any of the base classifiers after feature selection. It has to be noted that, at the theoretical level, the definition of efficiency only incorporates ability indirectly. That is the case because students who do not reach the end of the test cannot solve the corresponding items. Students who are going too fast are likely to fail as well. The resulting ability estimates, which are based on item success, hence, are indirectly incorporated in the efficiency label that is actually based on speeding criteria exclusively. Nevertheless, this indirect impact was not large enough for granting substantial predictivity to students’ ability for inferring their test-taking efficiency as specified by the competition.

It is apparent that the presented predictive modeling’s performance does not exceed a moderate level, if at all. This is similarly true for the competition winners. While behavioral predictions with temporal delay can always be expected to be weak, there seem to be multiple reasons inherent to the provided data set and challenge behind the moderate predictive classification performance. From our point of view, there are three major points that are worth following-up on in discussions. The most prominent one is the data reduction to twenty and ten minutes of log data for two thirds of the test data. The resulting leaderboard data evaluation was dominated by the secondary goal of predictions with less data. Also, since the different conditions shape the data and derived features quite differently, the training of classifiers had to be tailored to those.

The second important contribution is that the paper provides evidence that questions the target label’s validity. Using additional data sources from outside the information provided by the competition, we were able to re-engineer scores for estimating test taker ability. Importantly, feature selection led to excluding the ability feature, as it failed to be predictive of the efficiency label. This was a strong indicator for the suboptimal operationalization of efficiency.

This especially relates to the labeling of students as going too fast. To identify test takers spending a reasonable amount of time on a task, the competition organizers chose the 5th percentile of response times within an item as the threshold. Such a norm-oriented classification leads to labeling a fixed number of test takers as inefficient at each item, even when there are none or substantially less than 5 percent. Instead, criterion-based classification would be worthwhile. However, if corresponding criteria are not available, norm-oriented approaches would need to be combined with a dynamic threshold to be determined for each item, as the response time distributions of items typically differ considerably. The high ratio of 40 percent of students labeled as inefficient, which seems unreasonably high, is probably the result of this purely norm-based decision.

One option for identifying an appropriate threshold constitutes the visual inspection of distributions if little information about items are available. Often, response time distributions are bimodal. The first, very early peak is then typically associated with rapid guessing, while the second

Figure 3: Distributions of Speed (left) and Ability (right), Separated by Efficiency

Figure 4: Scatter Plot of Speed and Ability, Distinguishing Efficient and Inefficient Test Takers

peak corresponds to the actual response time mean of those test takers who did not exhibit rapid guessing behavior. The threshold would be set after the obvious extinction of the first peak [27]. For setting an actually accurate threshold, methods that combine response time, item information, and response accuracy are considered state of the art. For an overview see for example [26]. Further, the identification of thresholds should be guided by contextual considerations, judging for example whether false-positives or false-negatives are more acceptable in the context of the test.

An additional area of interest was that the binary label for efficiency mixes two types of students within its inefficient value: going too fast and going too slow. This has implications for the learning algorithms that have to optimize their parameters towards two different conditions within one class. Moreover, from a substantive perspective, this mixes at least two types of students: those who are disengaged—thus, either rushing or meandering pointlessly through the test—and those who are too thoroughly working, poorly monitoring their progress, or who are just less able.

6. CONCLUSION

One of the central messages of the competition is that predictions of test-taking efficiency are highly dependent on the definition, measurement, and evaluation of efficiency itself. That is true for the presented approach, as well as for other competition entrants, as seen through the leaderboard test set evaluation phase. In such a case, and if classifiers are meant to be put into productive usage, it is even more important from our point of view to have comprehensible models. Imagine a hypothetical situation when a teacher sees a student being flagged on a dashboard after 20 min of testing. The flag indicates the risk for inefficient test taking later on, but we know that the flag’s accuracy is fairly low. It is vital that the teacher is informed about the basis of the flag’s decision criteria. As we have shown, the competition’s target label classified some of the most able students as inefficient who by ability are reasonably quick in completing the tasks. The consequences of a teacher going to a successful, engaged student and telling them they should aim at being more engaged or efficient in their test taking, would be reasonably disruptive. It can be assumed that such an

invasive and intrusive test administrator behavior would be counterproductive and decrease, rather than improve data quality. If however, the included features for predictions are transparent, known, and understandable, the teacher could communicate those and contextualize the flag accordingly. A risk of more powerful black-box deep-learning classifiers is that a small to medium share of more accurately classified cases does not necessarily outweigh the resulting obscurity of classification mechanisms. More generally, the effects of the invasive disruption of a test administrator proactively trying to motivate test takers on the standardization of the assessment setting need to be studied. Moreover, before using such a measure, classifiers would need to be checked for biases towards certain subgroups in order to still adhere to standards of standardized assessments [1]. Overall, we would recommend to refrain from using such predictions with low to moderate accuracy in productive assessments as long as the effects of changes in the test administration are unknown.

Instead, the discussion section gives some insights into what could improve the setup of a more proper training data set for predictions. Mainly, a more representative definition of efficiency might be necessary, one that reflects the current scientific state of the art which factors in students' ability. Furthermore, the described psychometric and theory-driven perspective, together with the referenced tools, can be helpful for mining log data from assessments at the large scale while retaining the individual perspective. With the illustrated software package LogFSM, for example, we were able to identify test takers who clearly showed consistent inefficient behavior, but were labeled as efficient, and vice versa. These observations are constrained by the fact that the log data of Block B was not available, yet served as the basis for the evaluation of the efficiency label. However, we think that the number of these cases is too large for being an effect of temporal instability only. We believe that these analyses combined with more innovative machine learning designs that the educational data mining community can provide are promising for further improving the predictions of test-taking efficiency.

7. LIMITATIONS

The paper already highlighted the presented study's limitations over the course of the different sections. On top of the challenges inherent to the data competition, this study's main limitation constitutes the employment of baseline machine learning. Moreover, speed and ability have been estimated separately, whereas a simultaneous estimation might have been possible as well [23]. The selection of feature sets and learning algorithms was optimized towards the test set which turned out to provide rather unstable evaluations. The conclusion of this paper is that the NAEP Data Mining Competition for 2019 provided an important opportunity to further develop complex conversations about how educational data mining and psychometric modeling can support data quality of assessments by identifying disengaged test taking behavior.

ABSTRACT

Students acquire knowledge as they interact with a variety of learning materials, such as video lectures, problems, and discussions. Modeling student knowledge at each point during their learning period and understanding the contribution of each learning material to student knowledge are essential for detecting students' knowledge gaps and recommending learning materials to them. Current student knowledge modeling techniques mostly rely on one type of learning material, mainly problems, to model student knowledge growth. These approaches ignore the fact that students also learn from other types of material. In this paper, we propose a student knowledge model that can capture knowledge growth as a result of learning from a diverse set of learning resource types while unveiling the association between the learning materials of different types. Our multi-view knowledge model (MVKM) incorporates a flexible knowledge increase objective on top of a multi-view tensor factorization to capture occasional forgetting while representing student knowledge and learning material concepts in a lower-dimensional latent space. We evaluate our model in different experiments to show that it can accurately predict students' future performance, differentiate between knowledge gain in different student groups and concepts, and unveil hidden similarities across learning materials of different types.

knowledge tracing, domain modeling, tensor factorization, multi-view learning

1. INTRODUCTION

Both student knowledge modeling and domain knowledge modeling are important problems in the educational data mining community. In this context, student knowledge tracing and knowledge modeling approaches aim to evaluate students' state of knowledge or quantify students' knowledge in

the concepts that are presented in learning materials at each point of the learning period [15, 6, 51, 25, 53, 32, 14, 47]. Domain knowledge modeling, on the other hand, focuses on understanding and quantifying the topics, knowledge components, or concepts that are presented in the learning material [7, 12, 27]. It is useful in creating a coherent study plan for students, modeling students' knowledge, and analyzing students' knowledge gaps.

A successful student knowledge model should be personalized to capture individual differences in learning [51, 28], understand the association and relevance between learning from various concepts [42, 53], model knowledge gain as a gradual process resulting from student interactions with learning material [21, 38, 18], and allow for occasional forgetting of concepts in students [14, 32, 18]. Despite recent success in capturing these complexities in student knowledge modeling, a simple, but important aspect of student learning is still under-investigated: that students learn from different types of learning materials. Current research has focused on modeling one single type of learning resource at a time (typically, "problems"), ignoring the heterogeneity of learning resources from which students may learn. Modern online learning systems frequently offer students to learn and assess their knowledge using various learning resource types, such as readings, video lectures, assignments, quizzes, and discussions. Previous research has demonstrated considerable benefits of interacting with multiple types of materials on student learning. For example, worked examples can lead to faster and more effective learning compared to unsupported problem solving [33]; and enriching textbooks with additional forms of content, such as images and videos, increases the helpfulness of learning material [2, 1]. Ignoring diverse types of learning materials in student knowledge modeling limits our understanding of how students learn.

One of the obstacles in considering the combined effect of learning material types is the lack of explicit learning feedback from all of them. Some learning material types, such as problems and quizzes, are gradable. As students interact with such material types, the system can perceive student grade as an explicit feedback or indication of student knowledge: if a student receives a high grade in a problem, it is likely that the student has gained enough knowledge required to solve that problem. On the other hand, some of the learning materials are not gradable and their impact on student knowledge cannot be explicitly measured. For example, we cannot directly measure the consequent knowledge

*First two authors contributed equally to this work.

gain from watching a video lecture or studying an example.

As an alternative for quantifying student knowledge gain, the system can measure other quantities, such as the binary indication of student activity with a learning material or the time they spent on it. However, this kind of measure may result in contradictory conclusions [8, 23, 22]. For example, spending more time to study the examples provided by the system may both increase the student's knowledge, and at the same time, be an indicator of a weaker student, who does not have enough knowledge in the provided concepts. These weaker students may select to study more examples to compensate for their lower knowledge levels. Consequently, the knowledge gain of studying these auxiliary learning materials is usually overpowered by the student selection bias and is not represented correctly in the overall dataset.

A similar issue exists in the current domain knowledge models. The automatic domain knowledge models that are based on students' activities mainly model one type of learning material and ignore the relationship between various kinds of learning materials [17, 12]. Alternatively, an ideal domain knowledge model should be able to model and discover the similarities between learning materials of different types.

In this paper, we simultaneously address the problems of student knowledge modeling and domain knowledge modeling, while considering the heterogeneity of learning material types. We introduce a new student knowledge model that is the first to concurrently represent student interactions with both graded and non-graded learning material. Meanwhile, we discover the hidden concepts and similarities between different types of learning materials, as in a domain knowledge model. To do this, we pose this concurrent modeling as a multi-view tensor factorization problem, using one tensor for modeling student interactions with each learning material type. By experimenting on both synthetic and real-world datasets, we show that we can improve student performance prediction in graded learning materials, as measured by the Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE).

In summary, the contributions of this paper are:

- 1) proposing a personalized, multi-view student knowledge model (MVKM) that can capture learning from *multiple learning material types* and allow for occasional student forgetting, while modeling all types of learning materials;
- 2) conducting experiments on both synthetic and real-world datasets showing that our proposed model outperforms conventional methods in predicting student performance;
- 3) examining the resulting learning material and student knowledge latent features to show the captured similarity between learning material types and interpretability of student knowledge model.

2. RELATED WORK

Knowledge Modeling Student knowledge modeling aims to quantify student knowledge state in the concepts or skills that are covered by learning materials at each learning point.

Pioneer approaches of student knowledge modeling, despite being successful, were not personalized, relied on a predefined (sometimes expert-labeled) set of concepts in learning

material, did not allow for learned concepts to be forgotten by students, and modeled each concept independently from one another [19, 15, 36, 45]. Later, some student knowledge models aimed to solve these shortcomings by learning different parameters for each (type of) student [35, 51, 26], including decays to capture forgetting of concepts in learner models [39, 29, 31] and capturing the relationship between concepts that are present in a course [44, 21]. Yet, these models assume that a correct domain knowledge model, that maps learning material into course concepts, exists.

In recent years, new approaches aim to learn both domain knowledge model and student knowledge model at the same time [28, 20, 42, 48, 53, 18]. Our proposed model falls into this latest category as it does not require any manual labeling of learning materials, while having the ability to use such information if they are available. It is personalized by learning lower-dimensional student representations, allows forgetting of concepts during student learning by adding a rank-based constraint on student knowledge, and models the relationship between learning material.

Learning from Multiple Material Types In the educational data mining (EDM) literature, learning materials are provided in various types, such as problems, examples, videos, and readings. While there have been some studies in the literature on the value of having various types of learning materials for educating students [2, 8, 33], the relationship between these material types, and their combined effect on student knowledge and student performance is under-investigated.

Multiple learning material types have been studied in the literature in finding insights into different activity distributions or cluster patterns between high-grade and low-grade students [46, 49], have been used as contextual features in scaffolding or choosing among the existing student models [52, 43], have been added to improve existing domain knowledge models only for graded material types while ignoring student sequences [10, 13, 16, 30, 34, 41, 37], or have been classified into beneficial or non-beneficial for students [3]. However, to the best of our knowledge, none of these studies have explicitly modeled the contribution of various kinds of learning materials on student knowledge during the learning period, the interrelations among these learning materials, and their effect on student performance. The Bayesian Evaluation and Assessment framework found that assistance promoted students' long-term learning. More recently, Huang et al. discovered that adaptation of their framework (FAST) for student modeling by including various activity types may lead researchers to contradictory conclusions [23]. More specifically, in one of their formulations student example activity suggests a positive association with model parameters, such as probability of learning, while in another formulation this type of activity has a negative association with model parameters. Also, Hosseini et al. concluded that annotated examples show a negative relationship with students' learning, because of a selection effect: while annotated examples may help students to learn, weaker students may study more annotated examples [22]. The model proposed in this paper considers student interactions from multiple learning material types, mitigating over-estimation of student knowledge by transferring information from interactions with graded

material, while accounting for knowledge increase that happen as a result of student interaction with non-graded material.

3. MULTI-VIEW KNOWLEDGE MODELING

3.1 Problem Formulation and Assumptions

We consider an online learning system in which M students interact with and learn from multiple types ($r \in \mathcal{R}$) of learning materials. Each learning material type r includes a set of $P^{[r]}$ learning materials. A material type can be either graded or non-graded. Students' normalized grade in tests, success or failure in compiling a piece of code, or scores in solving problems are all examples of graded learning feedback. Whereas, watching videos, posting comments in discussion forums, or interacting with annotated examples are instances of non-graded learning feedback that the system can receive. We model the learning period as a series of student attempts on learning materials, or time points ($a \in \mathcal{A}$). To represent student interaction feedback with learning materials of each type r during the whole learning period \mathcal{A} , we use a $M \times P^{[r]} \times A$ three-dimensional tensor $\mathbf{X}^{[r]}$. The a^{th} slice of tensor $\mathbf{X}^{[r]}$, denoted by $X_a^{[r]}$, is a matrix representing student interactions with the learning material type r during one snapshot of the learning period. The s^{th} row of this interaction matrix $\mathbf{x}_{a,s}^{[r]}$ shows feedback from student s 's interactions with all learning materials of type r at attempt a ; and the tensor element $x_{a,s,p}^{[r]}$ is the feedback value of student s 's activity on learning material p of type r at learning point a .

We use the following assumptions in our model: (a) Each learning material covers some concepts that are presented in a course; the set of all course concepts are shared across learning materials; and the training data does not include the learning materials' contents nor their concepts. (b) Different learning materials have different difficulty or helpfulness levels for students. For example, one quiz can be more difficult than another one, and one video lecture can be more helpful than the other one. (c) The course may follow a trend in presenting the learning material: going from easier concepts to more difficult ones or alternating between easy and difficult concepts; despite that, students can freely interact with the learning materials and are not bound to a specific sequence. (d) As students interact with these materials, they learn the concepts that are presented in them; meaning that their knowledge in these concepts increases. (e) Since students may forget some course concepts, this knowledge increase is not strict. (f) Different students come with different learning abilities and initial knowledge values. (g) The gradual change of knowledge varies among different students. But, students can be grouped together according to how their knowledge changes in different concepts, e.g., some students are fast learners compared to others. (h) Eventually, a student's performance in a graded learning material, represented by a score, depends on the concepts covered in that material, student's knowledge in those concepts, the learning material difficulty/helpfulness, and the general student ability.

In addition to the above, we have an essential assumption (i) that connects the different parts of our model: a student's knowledge that is obtained from interacting with one learning material type is transferable to be used in other types of

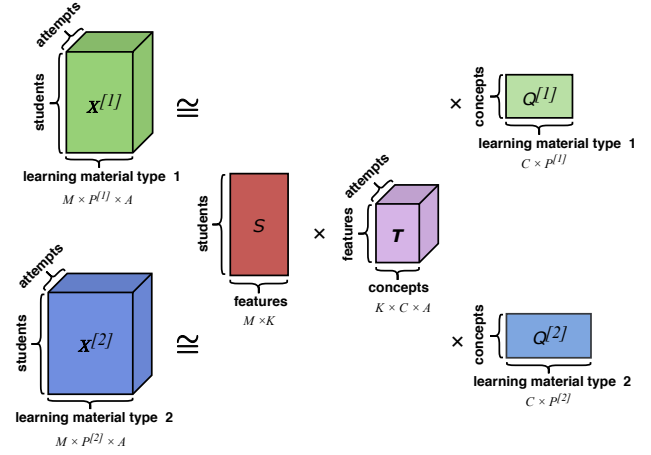

Figure 1: Decomposing student interaction tensors with two learning material types $\mathbf{X}^{[1]}$ and $\mathbf{X}^{[2]}$.

learning materials. In other words, students' knowledge can be modeled and quantified in the same latent space for all different learning material types. In the following, we first propose a single-view model for capturing the knowledge gained using one type of learning material (MVKM-Base) and then extend it to a multi-view model that can represent multiple types of learning materials.

3.2 MVKM Factorization Model

The Proposed Base Model (MVKM-Base). Following the mentioned assumptions in Section 3.1, particularly assumptions (a), (g), and (h), and assuming that students interact with only one learning material type, we model student interaction tensor \mathbf{X} as a factorization (n -mode tensor product) of three lower-dimensional representations: 1) an $M \times K$ student latent feature matrix S , 2) a $K \times C \times A$ temporal dynamic knowledge tensor T , and 3) a $C \times P$ matrix Q serving as a mapping between learning materials and course concepts. In other words, we have $\hat{x}_{s,a,p} \approx \mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p$. Matrix S here represents students being mapped to latent learning features that can be used to group the students (assumption (g)). Tensor T quantifies the knowledge growth of students with each learning feature in each of the concepts while attempting the learning material. Accordingly, the resulting tensor from product $\mathbf{K} = \mathbf{S}\mathbf{T}$ represents each student's knowledge in each concept at each attempt.

To increase interpretability, we enforce the contribution of different concepts in each learning material to be non-negative and sum to one. Similarly, we enforce the same constraints on each student's membership in the student latent features. Since each student can have a different ability (assumption (f)) and each learning material can have its own difficulty level (assumption (b)), we add two bias terms to our model (b_s for each student s , and b_p for each learning material p) to account for such differences. To capture the general score trends in the course (assumption (c)), we add a parameter b_a for each attempt. Accordingly, we estimate student s 's score in a graded learning material p at attempt a ($\hat{x}_{a,s,p}$) as in Equation 1. Here, T_a is a matrix capturing the relationship between student features and concepts at attempt a , \mathbf{s}_s represents student s 's latent feature vector, \mathbf{q}_p shows material p 's concept vector.

$$\hat{x}_{s,a,p} \approx \mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p + b_s + b_p + b_a \quad (1)$$

We use a sigmoid function $\sigma(\cdot)$ to estimate student interaction with a non-graded learning material, or graded ones with binary feedback:

$$\hat{x}_{s,a,p} \approx \sigma(\mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p + b_s + b_p + b_a)$$

Modeling Knowledge Gain while Allowing Forgetting. So far, this simple model captures latent feature vectors of students and learning materials, and learns T as a representation of knowledge in students. However, it does not explicitly model students' gradual knowledge gain (assumption (d)). We note that students' knowledge increase is associated with the strength of concepts in the learning material that they interact with. As students interact with learning materials with some specific concepts, it is more likely for their predicted scores in the relevant learning materials to increase. With a Markovian assumption, we can say that if students have practiced some concepts, we expect their scores in attempt $a+1$ to be more than their scores in attempt a :

$$\mathbf{s}_s \cdot T_{a+1} \cdot \mathbf{q}_p - \mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p \geq 0$$

However, this inequality constraint is too strict as the students may occasionally forget the learned concepts (assumption (e)). To allow for this occasional forgetting and soften this constraint, we model the knowledge increase as a rank-based constraint, that allows for knowledge loss, but penalizes it. We formulate this constraint as maximising the value for \mathcal{L}_2 in Equation 2. Essentially, this penalty term can be viewed as a prediction-consistent regularization. It helps to avoid significant changes in students' knowledge level since their performance is expected to transit gradually over time.

$$\mathcal{L}_2 = \sum_{j=1}^{a-1} \sum_{s,p} \log(\sigma(\mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p - \mathbf{s}_s \cdot T_j \cdot \mathbf{q}_p)) \quad (2)$$

The Proposed Multi-View Model (MVKM). We rely on our main assumption (i) to extend our model to capture learning from different learning material types. So far, we have assumed that course concepts are shared among learning materials (assumption (a)). With the knowledge transfer assumption (i), all learning materials of different types will share the same latent space. Also, we represent student knowledge and student ability as shared parameters across all different learning material types. Consequently, for each set of learning materials of type $r \in \mathfrak{R}$, we can rewrite Equation 1 as:

$$\hat{x}_{s,a,p}^{[r]} \approx \mathbf{s}_s \cdot T_a \cdot \mathbf{q}_p^{[r]} + b_s + b_p^{[r]} + b_a$$

An illustration of this decomposition, when considering two learning material types, is presented in Figure 1. Note that we represent one shared matrix student S and one shared knowledge gain tensor T in both types of learning materials.

We can learn the parameters of our model by minimizing the sum of squared differences between the observed ($x_{s,a,p}^{[r]}$) and estimated ($\hat{x}_{s,a,p}^{[r]}$) values over all learning material types $r \in \mathfrak{R}$. For the learned parameters to be generalizable to unseen data, we regularize the unconstrained parameters using their L-2 norms. As a result, we minimize the objective function in Equation 3, in which $\gamma^{[r]}$ are hyper-parameters that represent the relative importance of different learning materials types.

λ_t and λ_s are hyper-parameters to control the weights of regularization term of T and S .

$$\begin{aligned} \mathcal{L}_1 &= \sum_{r,s,a,p} \gamma^{[r]} (\hat{x}_{s,a,p}^{[r]} - x_{s,a,p}^{[r]})^2 + \lambda_t \|T_a\|_F^2 + \lambda_s \|\mathbf{s}_s\|_F^2 \\ \text{s.t. } &\forall_{r,c,p} \quad q_{c,p}^{[r]} \geq 0, \quad \sum_c q_{c,p}^{[r]} = 1 \end{aligned} \quad (3)$$

Similarly, the knowledge gain and forgetting constraint presented in Equation 2 can be extended to the multi-view model. Eventually, we use a combination of the reconstruction objective function (Equation 3) and the learning and forgetting objective function (Equation 2) to model students' knowledge increase, while representing their personalized knowledge and finding learning material latent features, as in Equation 4. Note that, since our goal is to minimize \mathcal{L}_1 and maximize \mathcal{L}_2 , we use $-\mathcal{L}_2$ to minimize \mathcal{L} . To balance between the accuracy of student performance prediction and modeling student knowledge increase, we use a nonnegative trade-off parameter ω :

$$\mathcal{L} = \mathcal{L}_1 - \omega \mathcal{L}_2 \quad (4)$$

We use stochastic gradient descent algorithm to minimize \mathcal{L} in Equation 4. The parameters need to learn are students' latent feature matrix (S), dynamic knowledge in each concept at any attempt (T), importance of each concept in every learning material ($Q^{[r]}$), each student's general ability (b_s), each learning material's difficulty/helpfulness ($b_p^{[r]}$), and each attempt's bias (b_a).

4. EXPERIMENTS

We evaluate our model with three sets of experiments. First, to validate if the model captures the variability of observed data, we use it to predict unobserved student performances (Sec. 4.3). Second, to check if our model represents valid student knowledge growth, we study the knowledge increase patterns between different types of students and across different concepts (Sec. 4.4). Finally, to study if the model meaningfully recovers learning materials' latent concepts, we analyze their similarities according to the learned latent feature vectors (Sec. 4.5). Without loss of generalizability, although the model is designed to handle multiple learning material types, we experiment on two learning material types. Before the experiments, we will go over our datasets, and experiment setup.

Table 1: Statistics for each datasets, where #stu is number of students, act. seq. len. is the maximum activity length, #rcds. is number of records that student interact with learning materials and avg. sco. is graded learning material's average score.

4.1 Datasets

We use three synthetic and three real-world datasets (from two MOOCs) to evaluate the proposed model. Our choice of real-world datasets is guided by two factors, aligned with

Figure 2: Histogram of graded materials' Scores in Synthetic Data and Real-World Data.

our assumptions: that they include multiple types of learning material, and that they allow the students to work freely with the learning material in the order they choose. In the real-world datasets, we select the students that work with both types of learning materials, removing the learning materials that none of these students have interacted with. General statistics of each dataset are presented in Table 1. Figure 2 shows score distributions of the graded learning material types in these datasets.

Synthetic Data. We generate three synthetic datasets according to two characteristics: (1) if both learning material types are graded vs. if one of them is non-graded (or has binary observations); (2) if the student scores are capped and their distribution is highly skewed vs. if the score distribution is not capped and less skewed.

For creating the datasets, we follow similar assumptions as to the ones made by our model. Expecting $P^{[1]}$ learning materials of type 1, and $P^{[2]}$ materials of type 2, we first generate a random sequence L_s for each student s , which represents the student's attempts on different learning materials. Considering C latent concepts, we then create two random matrices $Q^{[1]} \in \mathbb{R}^{C \times P^{[1]}}$ and $Q^{[2]} \in \mathbb{R}^{C \times P^{[2]}}$ as the mapping between the learning material and the C underlying concepts, such that the sum of values for each underlying learning material is one. For the student knowledge gain assumption, we represent each student's knowledge increase separately. Hence, we directly create a student knowledge tensor \mathbf{K} , instead of creating \mathbf{S} and \mathbf{T} , and multiplying them. To generate \mathbf{K} , we first generate a random matrix \mathbf{K}_1 that represents all students' initial knowledge in all C concepts. For generating the knowledge matrix in the next attempts (\mathbf{K}_a), we use the following random process. For each student s , we generate a random number α representing the probability of forgetting. If $\alpha > \theta$ (forgetting threshold), we assume no forgetting happens and increase the value in the knowledge matrix according to the learning material that the student has interacted with: $\mathbf{k}_{s,a} = \mathbf{k}_{s,a-1} + \beta \mathbf{q}_{L_s[a]}^{[r]}$. Here, β is a random effect of increasing and $L_s[a]$ is the learning material that student has selected to interact with at timestamp a . Otherwise ($\alpha < \theta$, or forget), we set $\mathbf{k}_{s,a,c} = \mathbf{k}_{s,a-1,c} - \text{rand}(0, \epsilon)$, for $\forall c \in C$. we use n-mode tensor product to build $\mathbf{X}^{[1]}$ and $\mathbf{X}^{[2]}$, where $\mathbf{X}^{[1]} = \mathbf{K}Q^{[1]}$, $\mathbf{X}^{[2]} = \mathbf{K}Q^{[2]}$. Finally, according to the student learning sequences L_s , we remove the "unobserved" values that are not in L_s from $\mathbf{X}^{[1]}$ and $\mathbf{X}^{[2]}$.

To create different data types according to the first characteristic above, for the graded learning material type r , we keep the values in $\mathbf{X}^{[r]}$. For the non-graded ones, we use the same process as above, except that in the final step we

set $x_{s,a,p}^{[r]} = 1$ according to the student sequence L_s . However, in many real-world scenarios, the score distribution of students is highly skewed especially towards higher scores (Figure 2 show it). To represent this skewness, in some of the generated datasets, we clip all $x_{s,a,p}^{[r]} > 1$ to 1.

Then, we create following three datasets according to above process: *Synthetic_G*, in which both learning material types are graded and scores are skewed; *Synthetic_NG*, in which one of the learning material types is graded and scores are skewed; and *Synthetic_NG2*, in which one of the learning material types is graded and scores are not skewed. We generate all synthetic data with 1000 students, $P^{[1]} = 10$ learning materials of type 1, $P^{[2]} = 15$ learning materials of type 2, $C = 3$ latent concepts, and maximum sequence length of 20 for students.

Canvas Network [11]. This is an online available dataset collected from various courses on the Canvas network platform¹. The available open online course data comes from various study fields, such as computer science, business and management, and humanities. For each course, its general field of study is presented in the data. The rest of the dataset is anonymized such that course names, discussion contents, student IDs, submission contents, or course contents are not available. Each course can have different learning material types, including assignments, discussions, and quizzes. We experiment on the data from one course in this system, with course id 770000832960975, which is in the humanities field (Canvas_H dataset). We use quizzes as the graded learning material type and discussions as the non-graded one.

MORF [4]. This is a dataset of the "educational data mining" course [5] at Coursera², available via the MOOC Replication Framework (MORF). The course includes various learning material types, including video lectures, assignments, and discussion forums. Students' history, in terms of their watched video lectures, submitted assignments, and participated discussions, in addition to the score they received in assignments, is available in data. In this course, we experiment with two datasets, each focusing on two sets of learning material types: one with assignments as the graded type and discussions as the non-graded type (MORF_QD), another with assignments as the graded type and video lecture views as the non-graded type (MORF_QL).

4.2 Experiment Setup

We use 5-fold student-stratified cross-validation to separate our datasets into test and train. At each fold, we use interaction records from 80% of students as training data. For the

¹<http://canvas.net>

²<https://www.coursera.org/>

rest (20%) of the students (target students), we split their attempt sequences on the graded learning material type into two parts: the first 50% and the last 50%. For performance prediction experiments, we predict the performance of the graded learning material type in the last 50%, given the first 50%. In order to see how the proposed model captures the knowledge growth, we do online testing, in which we predict the test data attempt by attempt (next attempt prediction). Eventually, we report the average performance on all five folds. For selecting the best hyper-parameters, we use a separate validation dataset. Our code and synthetic data are available at GitHub³.

4.3 Student Performance Prediction

In this set of experiments, we test our model on predicting student scores on their future unobserved graded learning material attempts. More specifically, we estimate student scores on their future attempts, and compare them with their actual scores in the test data.

4.3.1 Baselines

We compare our model with state-of-the-art student performance prediction baselines:

Individualized Bayesian Knowledge Tracing (IBKT) [24, 51]: This is a variant of the standard BKT model, which assumes binary observations and provides individualization on student priors, learning rate, guess, and slip parameters⁴.

Deep Knowledge Tracing (DKT) [38]: DKT is a pioneer algorithm that uses recurrent neural networks to model student learning, on binary (success/failure) student scores.

Feedback-Driven Tensor Factorization (FDTF) [40]: This tensor factorization model decomposes the student interaction tensor into a learning material latent matrix and a knowledge tensor. However, it only models one type of learning material, does not capture student latent features, and does not allow the students to forget the learned concepts. It assumes that students' knowledge strictly increases as they interact with learning materials.

Tensor Factorization Without Learning (TFWL): This is a model similar as FDTF, the only difference is TFWL does not have constraint that student knowledge is increasing.

Rank-Based Tensor Factorization (RBTF) [18]: This model has similar assumptions to FDTF. Except, it allows for occasional forgetting of concepts and has extra bias terms. Compared to MVKM, it does not differentiate between different student groups. It only uses student previous scores in graded learning materials to predict students' future scores, and it has a different tensor factorization strategy.

Bayesian Probabilistic Tensor Factorization (BPTF) [50]: This is a recommender systems model has a smoothing assumption over student scores in consecutive attempts.

AVG: This baseline uses the average of all students' scores for all predictions.

As mentioned before, one major issue in real-world datasets is their skewness, meaning that, on average, student grades are skewed towards a full (complete) score on quizzes/assignments. This skewness adds to the complexity of predicting an accurate score for unobserved quizzes: only using an overall average score will provide a relatively good estimate of

³<https://github.com/sz612866/MVKM-Multiview-Tensor>

⁴The code is from <https://github.com/CAHLR/pyBKT>

the real score. As a result, outperforming a simple average baseline is a challenging task.

The mentioned baselines all work on one type of learning material. Since our proposed MVKM model works with more than one learning material type, to be fair in evaluations, we run baseline algorithms in a multi-view setup. To do this, we aggregate the data from all learning material types and use that as an input to these baselines. In those cases, we add a "MV" to the end of their names. For example, FDTF_MV represents running FDTF on aggregation of student interactions with multiple learning material types. In addition, for knowledge tracing algorithms (BKT and DKT) which are designed for binary student responses (correct or incorrect), we modify their settings to make them predict numerical scores as described below. First, we binarize students' historical scores based on median score. Specifically, if the score is greater than the median, it will be set to 1, and 0 otherwise. Then, we use the probability of success generated by BKT and DKT as the probability of student receiving a score more than median score. Eventually, the numerical predicted scores can be obtained by viewing the probability output as the percentile of students' score on that specific question. Moreover, since these models require pre-defined knowledge components (KCs), we assume that each learning material is mapped to one KC in these models.

In addition to the above, we compare our multi-view model with its basic variation (MVKM-Base) using the data from graded materials only, and its multi-view variation without the learning and forgetting constraints (MVKM-W/O-P).

4.3.2 Performance Metrics and Comparison

In this task, our target is to accurately estimate the actual student scores. To evaluate how close our predicted values are to the actual ones, we use Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE) between the predicted scores and the actual scores for students. Table 2 and 3 show the results of performance among different methods on synthetic data and real data, respectively. We can see that our proposed model outperforms other baselines on synthetic data, and has the best performance on real datasets in general.

MVKM-Base vs. Single Material Type Baselines.

Comparing MVKM-Base with other algorithms that use student scores only, shows us that MVKM-Base has consistently lower error compared to most baselines, in both synthetic and real-world datasets. This result demonstrates the ability of MVKM-Base in capturing data variance and validity of its assumptions for real-world graded data. Compared to AVG, MVKM-Base can represent more variability; compared to RBTF, the student latent features in MVKM-Base leads to improved results; compared to FDTF, the forgetting factor results in less error; and compared to BKT and DKT, modeling the learning material concepts in Q and having a rank-based constraint to enforce learning improves the performance. The only baseline algorithm that outperforms MVKM-Base in some setups is BPTF. Particularly, BPTF has a lower RMSE and MAE in Synthetic_NG and Synthetic_G datasets that are skewed. In real-world datasets, it performs better than MVKM-Base in MORF-QD dataset that is more sparse and has a slightly higher average score

Table 3: Performance Prediction results on real-world datasets, measured by RMSE and MAE, shown with variance in 5-fold cross-validation.

compared to the other two. This shows that BPTF is better than MVKM-Base in handling skewed data. One potential reason is BPTF’s smoothing assumption, in contrast with MVKM-Base’s rank-based knowledge increase, that results in a more homogeneous score predictions for each student.

MVKM: Multiple vs. Single Material Types. Comparing MVKM’s results with MVKM-Base model, we can see that using data from multiple learning material types improves performance prediction results. It verifies our assumptions regarding knowledge transfer in different learning material types through the knowledge gain in shared concept latent space. This is given that in other models, e.g., all models except DKT in MORF-QD, adding different learning material types increases the prediction error. This error increase is particularly happening with BPTF model in real-world datasets and DKT model in synthetic ones. This shows that merely aggregating data from various resources, without appropriate modeling, can even harm the prediction results. This difference between MVKM and other baselines is in its specific setup, in which each learning material type is modeled separately, while keeping a shared knowledge space, student latent features, and knowledge gain.

Learning and Forgetting Effect. To further test the effect of our knowledge gain and forgetting constraint, we compare MVKM with MVKM-W/O-P, a variation of our

proposed model without the rank-based constraint in Equation 2. We can see that MVKM outperforms MVKM-W/O-P in all datasets. This shows that the soft knowledge increase and forgetting assumption is essential in correctly capturing the variability in students’ learning. Particularly, comparing MVKM-W/O-P’s results with MVKM-Base, the single-view version that includes the rank-based learning constraints, we can measure the effect of adding multiple learning material types vs. the effect of adding the learning and forgetting constraints in MVKM model. In CANVAS_H dataset, adding multiple learning material types is more effective than learning constraint, and in MORF datasets, realizing learning constraint is more important than modeling multiple types of learning materials. Nevertheless, they are not mutually exclusive and both are important in the model.

Hyper-parameter Tuning Using a separate validation set, we experiment with various values (grid search) for model hyper-parameters to select the most representative ones for our data. Specifically, we first vary the student latent feature dimension K in $[1, 5, 10, \dots, 40, 45]$, the question latent feature dimension C in $[1, 2, \dots, 9, 10]$, the penalty weight ω in $[0.01, 0.05, 0.1, 0.5, 1, 2, 3]$, the Markovian step m in $[1, 2, \dots, 10]$, and the learning resource importance parameter $\gamma^{[r]}$ in $[0.05, 0.1, 0.2, 0.5, 1, 2]$. Once we found a good set of hyper-parameters from coarse-grained grid search, we search the values close to the optimal values to find out the

best fine-grained values for these hyper-parameters. The best resulting hyper-parameter values for each dataset are listed in table 4. We use $\gamma^{[1]}$ as the trade-off parameter for graded learning material, $\gamma^{[2]}$ for another learning material. As we can see, in both the synthetic and real-world data, the learning and forgetting constraint is more important (larger ω) when having a non-graded learning material type. This shows that binary interaction data, unlike student grades (or scores), is not precise enough to represent the students' gradual knowledge gain in the absence of a learning and forgetting constraint. Also, comparing $\gamma^{[2]}$ in MORF_QD vs. MORF_QL we can see that the importance of video lectures is more than discussions in predicting students' performance.

Dataset	K	C	ω	$\gamma^{[1]}$	$\gamma^{[2]}$	η	m	λ_t	λ_s
Synthetic_NG	3	3	0.2	1	0.1	0.1	1	0.01	0.001
Synthetic_NG2	3	3	0.2	1	0.1	0.1	1	0.001	0.001
Synthetic_G	3	3	0.1	1	0.4	0.1	1	0.001	0.001
MORF_QD	39	5	1	1	0.05	0.1	1	0	0

Canvas_H	28	7	2.0	1	0.5	0.01	1	0	0

Table 4: Hyperparameters of our model for each dataset

4.4 Student Knowledge Modeling

In this set of experiments, we answer two main research questions: 1) Can our model's learning and forgetting constraint capture meaningful knowledge trends across concepts for students as a whole? and 2) Are the individual students' knowledge growth representative of their learning? To answer these questions, we look at the estimated knowledge tensor of students ($\mathbf{K} = \mathbf{ST}$).

Figure 3: Average knowledge gain of concepts across all students.

To answer the first question, we check the average student knowledge growth on different concepts. Figure 3 shows the average knowledge of all students in different concepts (represented with different colors) during the whole course period (X-axis) for MORF_QL, and CANVAS_H datasets (MORF_QD has similar patterns as MORF_QL, we don't show it due to the page limitation). Notice that, for a clear visualization, we only show 3 out of 9 concepts from MORF_QL dataset in the figure. We can see that, on average, students' knowledge in different concepts increase. Particularly, in MORF_QL, the initial average knowledge on concept 3 is less than concepts 5 and 7. However, students learn this concept rapidly as shown by the increase of knowledge level around the tenth attempt. As the knowledge growth is less smooth in this concept, compared to the other two (e.g., the drop around the 15th attempt), students are more likely to forget it rapidly. Eventually, the average student knowledge in all concepts are close to each other. On

the other hand, in CANVAS_H, the average initial knowledge in different concepts are relatively close. However, students end up having different knowledge levels in different concepts at the end of the course, especially in concepts 0 and 4. Also, all six concepts show large fluctuations across the attempts. Overall, the students have a significant knowledge gain at the first few attempts and the knowledge gain slows down after that. This is aligned with our expectation on students' knowledge acquisition through out the course.

Figure 4: Average knowledge gain of each concept across all students.

To show the effect of the learning and forgetting constraint in MVKM, we look at the student knowledge acquisition in the MVKM-W/O-P model, that removes this constraint. The MVKM-W/O-P's average student knowledge in different concepts throughout all attempts is shown in Figure 4. We can see that despite its acceptable performance prediction error, MVKM-W/O-P's estimated knowledge trends are elusive and counter-intuitive. For example, many concepts (such as concept 3 in MORF_QL) show a U-shaped curve. This curve can be interpreted as the students having a high prior knowledge in these concepts, but forgetting them in the middle of the course, and then re-learning them at the end of the course. In some cases, such as concept 1 in CANVAS_H, students lose some knowledge and forget what they already knew, by the end of the course. This demonstrates the necessity of learning and forgetting penalty term in MVKM.

For second question, we check if there are meaningful differences between knowledge gain trends of different students. To do this, we apply spectral clustering on students' latent features matrix \mathbf{S} to discover different groups of students. Then, we compare students' learning curves from different clusters. The number of clusters is determined by the significance of difference on average performance in each cluster. We obtained 3 clusters of students for MORF_QD course, and 2 clusters for MORF_QL and CANVAS_H courses based on students' latent features from our model.

To see the differences in these groups, we sample one student from each cluster in each real-world dataset. Figure 5 shows these sample students' knowledge gain, averaged over all concepts, in datasets MORF_QD and MORF_QL (CANVAS_H is not showed due to the page limitation, it has similar patterns as MORF_QD). The figures show that different students start with different initial prior knowledge. For example, in MORF_QL, student #5 starts with a lower prior knowledge than student #100 and ends up with a lower final knowledge. Also, the figure shows that different knowledge gain trends across students, particularly in MORF_QD. For

Figure 5: Sample students' knowledge gain across all concepts in two different courses.

example, student #0 starts with a lower prior knowledge than the other two students, but has a faster knowledge growth, and catches up with them around attempt 8. However, this student's knowledge growth slows down after a while and ends up to be lower than the other two at the end of course. To see if the quantified knowledge is meaningful, we compare student's knowledge growth with their scores. Students #0, #8, and #189 in MORF_QD have average grades 0.202, 0.636, and 0.909, in MORF_QL, #5 and #100 have average grades 0.9 and 0.98. This aligns with the knowledge levels shown in the figure. These observations show that MVKM can meaningfully differentiate between different students' knowledge growth.

4.5 Learning Resource Modeling

In this section, we evaluate our model on how well it can represent the variability and similarity of different learning materials. We mainly focus on two questions: 1) Are the learning materials' biases consistent with their difficulty levels? 2) Are the discovered latent concepts for learning materials (matrix $Q^{[r]}$) representative of actual conceptual groupings of learning materials in the real datasets?

Bias Evaluation. For the first question, since we do not have access to the learning materials' difficulty levels, we use average student scores on them, as a proxy for difficulty. As a result, we only use graded learning materials for this analysis. We calculated the spearman correlation between question bias captured by our model and average score of each question. The spearman correlation on MORF_QD is 0.779, on MORF_QL is 0.597, and on CANVAS_H is 0.960. We find that question bias derived from MCKM is highly correlated with average question score, where the lower the actual average grades are, the lower the bias values are learned.

Within-Type Concept Evaluation. For the second question, we would like to know how much the learning materials' discovered latent concepts resemble the real-world similarities in them. To evaluate the real-world similarities, we rely on two scenarios: 1) the learning material that are arranged closely to each other in the course structure, either in same module or in consequent modules, are similar to each other (course structure similarity); 2) the learning materials that are similar to each other have similar concepts and contents (content similarity). Since only one of our real-world datasets, MORF_QL, includes the required information for these scenarios, we use this dataset in the continuation of this paper. For first scenario, the course includes an ordered list modules, each of which include an ordered list of videos,

in addition to the assignments associated with each module.

For the second scenario, because our learning materials are not labeled with their concepts in our datasets, we use their textual contents (not used in MVKM) as a representation of their concepts. Particularly, we have subscripts for 40 video lectures, and text of questions for 8 quizzes. We note that if two learning materials present the same concepts, their textual contents should also be similar to each other. As a result, we build content-based clusters of learning materials, each of which containing the learning materials that are conceptually similar to each other. Specifically, to cluster the learning material according to their contents, we use Spectral Clustering on the latent topics that are discovered using Latent Dirichlet Analysis (LDA)[9] on the learning material's textual contents. In the same way, we can cluster the learning materials according to their discovered latent concepts by MVKM. Similar to the textual analysis, we use spectral clustering on the discovered $Q^{[r]}$ matrices to form clusters of learning materials. To do this, we first consider only one learning material type (the video lectures) and then move on to the similarities between two types of learning materials (both video lectures and assignments).

The results are shown in Figure 6 for within-type learning material similarity in video-lectures. Figure 6(a) shows the 8 clusters that were discovered using MVKM, and Figure 6(b) shows the 8 clusters that were discovered using video-lecture transcripts. Each cluster is shown within a box with a number associated with it. Each video-lecture is shown by its module (or week in the course), its order in the module sequence, and its name. For ease of comparison, we colored the video names according to their LDA content clusters. Looking at the LDA content clusters, we can see that although some lectures in same module fit in same cluster (e.g., videos 1, 2, 3, and 4 from week 7 are all in cluster 7), some of the lectures do not cluster with other videos in their module. For example, video 5 in week 7 is in cluster 2, with pioneer knowledge tracing methods. This shows that in addition to structural similarities, content similarities also exist in learning materials. Looking at MVKM clusters, we can see that the clusters mostly represent the course structure similarity: learning materials from same module are grouped. For example, all videos of week 3 are grouped in cluster 2. However, we can see that in many cases, whenever the structure similarity in clusters are disrupted, it is because of the content similarity in video lectures. For example, video 5 in week 7 that was clustered with pioneer knowledge tracing method in LDA content clusters is also clustered with them in MVKM clusters.

Between-Type Concept Evaluation. To evaluate MVKM's discovered similarities between different types of learning materials, we evaluate assignments' and video lectures' in MORF_QL. To do this, we build LDA-based clusters using assignment texts and video lecture transcripts. These clusters are shown in Figure 7(b). We also cluster the learning materials using spectral clustering on the concatenation of their $Q^{[r]}$ matrices (Figure 7(a)). Because the assignments bring more information to the clustering algorithms, the clustering results are different from the clusters of video lectures only. Similar to within-type concept evaluation results, we can still see the effect of both content and structure

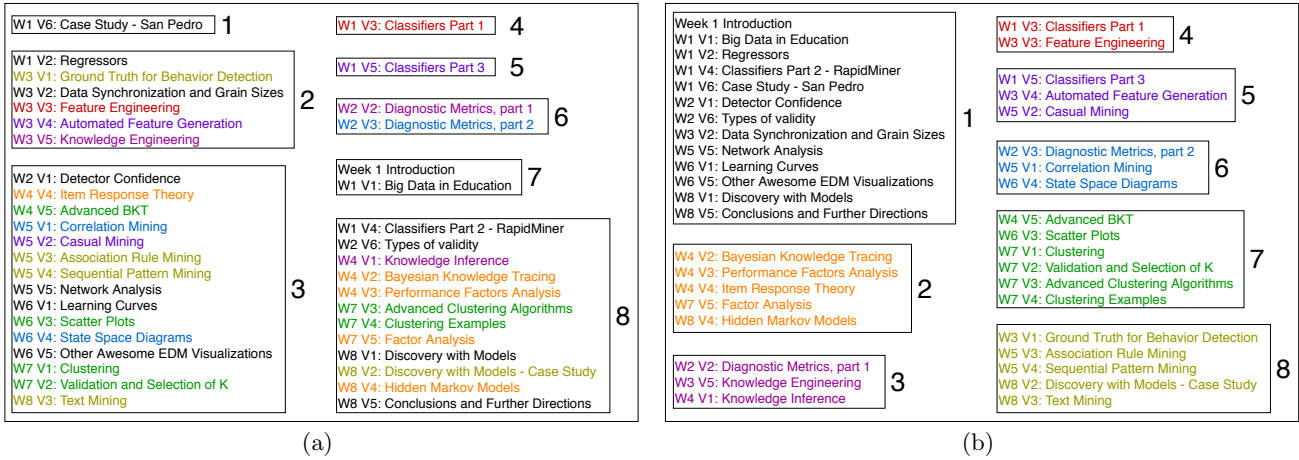

Figure 6: Clusters that were discovered by using MVKM (a), clusters discovered by using video-lecture transcripts (b).

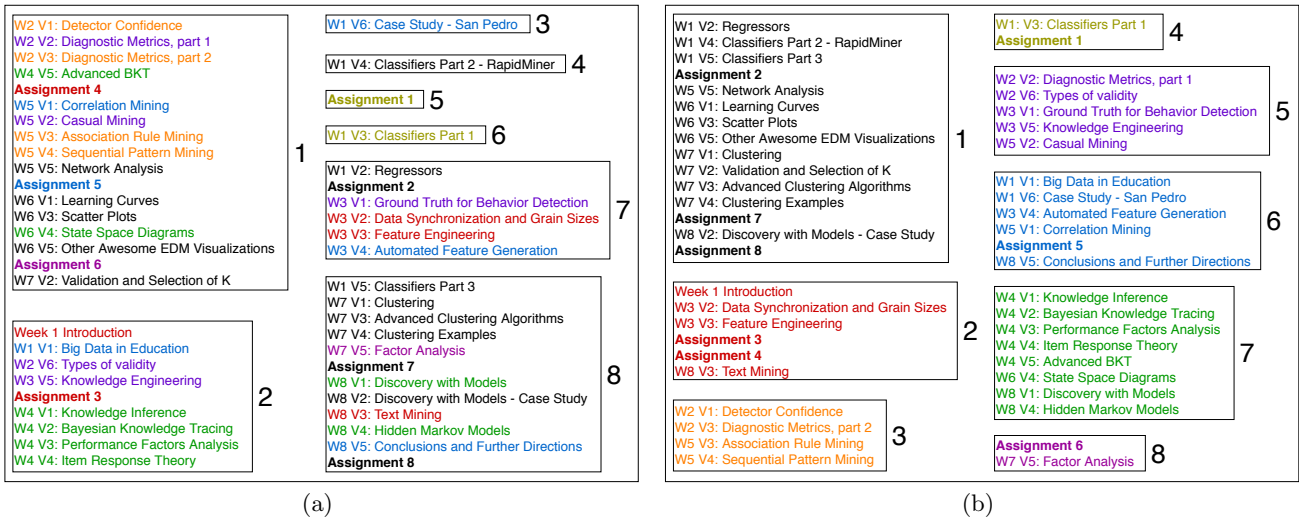

Figure 7: Clusters discovered by using MVKM (a), clusters discovered by using video-lecture transcripts and assignment texts(b).

similarities in video lectures that are clustered together by MVKM. For example, videos 1 and 3 of week 2 are clustered with later weeks' videos because of content similarity (cluster 1 in Figure 7(a)). While videos 2 of week 2 is also clustered with them because it comes between these two videos in course sequence.

Additionally, between video lectures and assignments, the clusters closely follow the course structure. The assignments in this course come at the end of their module and right before the next module starts. For example, "Assignment 3" appears after video 5 at week 3 and before video 1 at week 4. We can see that all assignments, except "Assignment 1" that is the first one, are clustered with their immediate next video lecture. Moreover, we can see the effect of content similarity between assignments and video lectures in differences of Figures 6(a) and 7(a). For example, without including assignments, "Week 1 Introduction" and "W1 V1: Big Data in Education" were clustered together in cluster 7 of Figure 6(a). However, after adding assignments, because of the content similarity between "Assignment 3" and "Week 1 Introduction" (Figure 7(b) cluster 2), "Week 1 Introduction" and "W1 V1: Big Data in Education" are clustered with video lectures that are structurally close to "Assignment 3".

Altogether, we demonstrated that learning materials' bias parameters in MVKM are aligned with their difficulties; learning materials' latent concepts discovered by our model well represent learning materials' real-world similarities, both in structure and in content; and MVKM can successfully unveil these similarities between different types of learning materials, without observing their content or structure.

5. CONCLUSIONS

In this paper, we proposed a novel Multi-View Knowledge Model (MVKM) that can model students' knowledge gain from different learning materials types, while simultaneously discovering materials' latent concepts. Our proposed tensor factorization model explicitly represents students' knowledge growth and allows for occasional forgetting of learned concepts. Our extensive evaluations on synthetic and real-world datasets show that MVKM outperforms other baselines in the task of student performance prediction, can effectively capture students' knowledge growth, and represent similarities between different learning materials types.

ABSTRACT

Predicting student success in a data science degree program is a challenging task due to the interdisciplinary nature of the field, the diverse backgrounds of the students, and an incomplete understanding of the precise skills that are most critical to success. In this study, the applicant's future academic performance in a Master of Data Science program is assessed using information from the admission application, such as standardized test scores, undergraduate grade point average, declared major, and school ranking. Simple data analysis methods and visualization techniques are used to gain a better understanding of how these variables impact student performance, and several classification algorithms are used to induce models to distinguish between students that will perform very well and those that will perform very poorly. Historical admissions and grading data are used to perform these analyses and build the classification models. The analyses and predictive models that are generated provide insight into the factors that identify good and poor candidates, and can aid in future admissions decisions.

Keywords

Admission decision making, Master's program, data science, learning assessment, machine learning.

1. INTRODUCTION

Data mining methods are now in widespread use in many industries, from healthcare[10] to business[15]. Data mining is increasingly applied to education [3][8][14] and includes many diverse applications, all of which fall under the area of educational data mining (EDM). A particular focus of

such applications is the college admissions process and its effectiveness, since this process directly affects the reputation of the institution as well as its financial well-being. Examples of work in this area include predicting college admissions yield [5], student retention[11], and enrollment management[1]. Another related area of EDM relates to predicting student performance. One such study used student personal and social factors, along with academic performance data, to identifying poor performers early on[2], while another study used similar information to predict third semester academic performance [13]. One more study used student course data during the semester (attendance, homework scores, etc.) to predict the student score on the end of the semester examination[18].

In this paper we investigate the problem of identifying a good admissions strategy for a Master's of Science program in Data Science (MSDS), so that the students that are admitted into the program will perform well. This problem is generally related to the EDM admissions topic, but also to the topic of predicting student performance. This problem is interesting, and distinctive, for a variety of reasons. One reason is that the vast majority of applications of data mining to college admissions deals with undergraduate admissions. That admissions process is very different from the process for our MSDS program, since undergraduate admissions is controlled by full-time admissions professionals, whereas admissions for our MSDS program is controlled by faculty with little time to devote to admissions, and who lack specialized admissions training. This is true for most graduate programs, except for possibly the large professional schools (e.g., law, medicine) that may admit many more students and have deeper resources. Determining admission to MSDS programs is especially challenging since it is an interdisciplinary field that attracts applicants from diverse backgrounds, and because MSDS programs were introduced only recently and hence have limited historical knowledge to leverage. Furthermore, even experts in the area do not fully understand exactly which undergraduate skills are most critical to success, so it is hard to know which students to admit or reject.

Yijun Zhao, Qiangwen Xu, Ming Chen and Gary Weiss "Predicting Student Performance in a Master's Program in Data Science using Admissions Data" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 325 - 333

The goal of this data mining task is to determine if, using only information available in the admissions application, a student will perform very well in the program, and hence deserve merit-based aid, or perform very poorly and hence should not be admitted. At this time only structured data is utilized in order to simplify the classification task. Thus external recommendations, personal statements, and resumes are not considered. However, there is still a wealth of information that is available, which includes prior degrees and associated grades, the name and country of the prior educational institutions, standardized test scores such as the GRE (Graduate Record Examination) and TOEFL (Test of English as a Foreign Language), and personal information about the applicant such as age, nationality, work history, and whether they ask for merit-based financial aid.

The purpose of this study is not just to identify which students will perform very well or very poorly, but to better understand the relevant factors. Thus, the predictive model that we build will most likely not be used for automated decision making, but instead will be used to educate the admissions committee about which factors are most relevant for success in the program. As mentioned earlier, this is especially important for the MSDS degree because the applicants have such different backgrounds and because the degree is relatively new.

A practical issue that impacts this study is that because the offered degree was launched only a few years ago, the data is quite limited. Compounding this issue is the fact that we do not have outcomes for students who are accepted but do not attend the university, and worse yet, we cannot know anything about how students who are rejected from the program would perform. One of our long term goals is to fully utilize this unlabeled data to improve the admissions process. This is discussed later in this paper as future work.

The rest of the paper is organized as follows. We present the details of our dataset in Section 2. The design of our experiments and associated methodology are presented in Section 3. Section 4 presents our experimental results and predictive factor analysis. We conclude and suggest future work in Section 5.

2. THE DATA

This section describes the data utilized in this study. Section 2.1 describes the data at a high level and includes some summary statistics, while Section 2.2 describes the features included in each application record. Section 2.3 then describes the distribution of feature values for key features, while Section 2.4 describes how these feature values relate to student performance in the MSDS program.

2.1 Overview

The data in this study is extracted from the application data provided by each applicant to Fordham University's MSDS program. The application process is completely electronic, so the underlying data was already in electronic form. Much of this data is structured data (e.g., student GRE scores) that is already parsed and readily available for extraction. However, other information, such as the student's required statement of purpose and external recommendations, are un-

structured text and would require substantial effort to exploit. This study is limited to structured data.

The data set is comprised of 826 applicant records. Of this total, 503 (60.9%) applicants were accepted into the program and 323 (39.1%) were rejected. Of the 503 accepted applicants, 132(26.2%) enrolled in the program while 371 (73.8%) did not enroll. Since only students who enrolled have grade information, the main analyses presented in this paper are based on only 132 records. Note that the data used in these analyses depends on our current admissions strategy, since it is possible that some of the students who were denied admission into the program could have performed well in the classes. The best we can do with respect to the population of students who were denied admission is to compare their characteristics with those of the students who enrolled and performed poorly; if it turns out that the factors used to determine admission into the program differ from those that tend to predict good performance, then the current admissions strategy should be modified. The characteristics of each student population are explored and compared in Section 2.3.

2.2 Features and Feature Generation

The features that are extracted from the student applications and used in this study are listed in Table 1, along with sample values. The first three features describe the Graduate Record Examination (GRE) standardized test scores and are encoded using the score percentile. The fourth feature describes the Test of English as a Foreign Language (TOEFL) total score. The next field specifies the number of months from the time of completion (or projected completion) of the last degree to the time the current application was submitted. For students who plan to start the MSDS program immediately following the graduation from their current program, this value is typically a negative six months. Student age is at the time of application and marital status is single, married, divorced, domestic partner, or blank (unspecified). Gender is either male or female and citizenship specifies the country of citizenship. The next six features relate to the last degree program (i.e., school) that the student attended. They include the student's GPA (Grade Point Average), major and degree, the country that the school resides in, the primary language of instruction, and the school ranking. The MSDS GPA uses a 4-point scale, and is based on the student's performance after enrolling in the program. This attribute is utilized to generate the class value, as described in Section 3.1.

School rank is the only feature in Table 1 that is not a feature from the student application. Instead, the ranking is generated from the school name via a multi-step process. The first step involves matching the school name against the US News and World Report "Best Global Universities" ranking ([usnews.com/education/best-global-universities](https://www.usnews.com/education/best-global-universities)), which includes 1500 universities from eighty countries and is based on academic research performance and global and regional reputation. If a match is found, then this global ranking is used; otherwise the US News and World Report "Best Colleges" ranking is searched ([usnews.com/best-colleges](https://www.usnews.com/best-colleges)). This is restricted to colleges in the United States and includes separate rankings for national universities (major research institutions), liberal arts colleges, and regional

Table 1: Data Set Features and Sample Values

#	Feature Name	Sample Value
1	GRE Verbal %	52
2	GRE Quantitative %	95
3	GRE Writing %	34
4	TOEFL Total	105
5	Months since Degree	6
6	Student Age	22
7	Marital Status	Married
8	Gender	M
9	Citizenship	China
10	School GPA	3.7
11	School Major	Chemical Engineering
12	School Degree	BS
13	School Country	China
14	School Language	Mandarin
15	School Rank	85
16	MSDS GPA	3.5

colleges and universities. If a match is found in one of these rankings, then the ranking is converted to a global ranking by adding 1200 if the match was for a national ranking, and 1400 if the match was for a regional ranking. This process of assigning a global ranking is a very rough heuristic method, but generally provides reasonable values. If a school is not found on any of these rankings then a global ranking of 9999 is used.

There are a number of features that are available from the original application information but are not used in this study and do not appear in Table 1. For example, the Total TOEFL score is included but the four TOEFL subscores are not included, since preliminary analysis indicated that these subscores did not provide much benefit. Additionally, if the applicant attended multiple institutions of higher education, then information for more than one school was provided. However, since providing additional schools for only some applicants would substantially complicate the analysis, this information was dropped, so only the most recent degree granting school was included.

2.3 Distribution of Feature Values

In any applied data mining study, it is important to understand the data. In this section, we provide information about the distribution of feature values. Since the focus of this study is in identifying students who will perform well or poorly in the program, we begin with the feature distribution of the students who enrolled in the MSDS program. This information is provided in Figure 2.2. The figure provides a good overview of the demographics of the applicants: males outnumber females by a ratio of almost 2 to 1, nearly 90% are single, and based on citizenship, about 74% are foreign nationals, while 21% are US citizens, and 5% are permanent residents. Clearly the MSDS program attracts a large international contingent. As expected, most students are young, although about 6% are over 30, suggesting that they likely have substantial industry experience. Overall, more than 80% are within two years of their last degree.

The TOEFL scores, which are only required for international students who have not completed two years of instruction

at an English-language university, show that most students, but not all, have good English language skills. According to the testing agency, the average TOEFL score is 84, and any such score is generally considered good. For the MSDS program, a score of 80 or above is generally required, and hence our admitted students tend to have good English language skills.

A feature that is critical to the admissions decision is the student's prior major discipline. The program is geared towards students who have substantial mathematics background and at least some experience in computer science and programming. While computer science and mathematics majors are thought to have an advantage, students in any science or quantitative discipline are encouraged to apply. Figure 2.2 shows the distribution of major over all applicants, and further shows the number in each major that were admitted and rejected. The statistics show that the largest number of admitted students have a background in computer science or a highly related field, with mathematics and statistics a close second.

Although this study focuses on enrolled students, it is useful to understand the characteristics of the students who were rejected from the program, or were admitted and did not enroll, and how they compare to students who did enroll. Displaying this information graphically for all three populations would take up too much space, so the key observations are summarized below.

- Applicants who were rejected are much more likely to have a GPA under 3.0 (41%) than those who enrolled (14%) or were admitted and did not enroll (17%).
- Applicants who were rejected are more likely to have a degree from an institution not ranked in the top 2000 (30.7%) than those who enrolled (25.8%) or were admitted but did not enroll (20.2%).
- Applicants who enrolled were about 6% more likely to have completed a graduate degree (21.2%) than those who were admitted but did not enroll (15.1%) or were rejected (14.6%).
- Applicants who enrolled were less likely to be female (35.6%) than those who were admitted but did not enroll (47.4%) or were rejected (39.6%). Female applicants who are admitted are less likely to enroll than their male counterparts.
- Foreign nationals made up 74% of enrolled students, 79% of those admitted who did not enroll, and 77% of those rejected. As might be expected, foreign nationals who are admitted are somewhat less likely to attend.
- The age profile does not vary much between those applicants who enroll and are rejected. However, applicants who enroll are much more likely to be older and between the ages of 24 and 30 (33%) than those who are admitted but do not enroll (22%).
- Those who apply more than two years after completing their last degree are more likely to be rejected from the program (33.3%) than those who either enroll (17%) or are admitted and do not enroll (19%).

Figure 1: Feature Statistics

Figure 2: Major Distribution

Table 2: Mean Values for MSDS Performance Groups

Feature	Bottom 20%	Middle 60%	Top 20%	All
GRE Verbal %	42.5	48.6	57.0	49.4
GRE Quantitative %	<u>79.0</u>	81.9	<u>82.8</u>	81.6
GRE Writing %	32.5	31.2	34.0	32.0
TOEFL Total %	96.1	96.1	96.6	96.2
Foreign National %	<u>59.1</u>	74.4	<u>85.7</u>	74.2
Graduate Degree %	<u>18.2</u>	19.5	<u>28.6</u>	21.2
Married %	22.7	9.8	14.3	12.9
Female %	22.7	39.0	35.7	35.6
Months Since Degree	<u>12.8</u>	13.6	<u>22.8</u>	15.4
Age	25.5	24.7	24.6	24.8
School Rank	1005	1005	1082	1005
School GPA	<u>3.17</u>	3.29	<u>3.53</u>	3.32

2.4 Features and MSDS Performance Groups

In Section 2.3 the distribution of feature values was examined for the population of enrolled students, and then the key differences between the features for the three admission categories (enrolled, admit but not enrolled, rejected) was analyzed. In this section, we compare the feature values with respect to student performance in the MSDS program to provide insight into the factors that influence student performance. As will be discussed in Section 3.1, our focus in this study is to identify the students who enroll in the MSDS program that will perform in the top 20% and the bottom 20%. Thus, in this section, we examine the feature values for three performance groups: the bottom 20%, middle 60%, and top 20%. In order to simplify the comparison, the mean values of numerical features are considered. Table 2 provides the relevant information. The features values that differ substantially between the bottom and top 20%, and we believe are of predictive value, are underlined.

The three GRE test score percentiles in Table 2 show the expected trend: the scores improve as we move up the performance groups. The one exception is that there is a slight dip in the GRE writing score when moving from the bottom group to the middle group, but even in this case the writing scores for the top group outperform the bottom group. Our admissions committee normally places the most weight on the quantitative score and generally does not consider the writing score. What is most interesting is that the difference in the quantitative scores between the bottom and top 20% is only 3.8% (79.0% vs. 82.8%), even though quantitative abilities are generally thought to be critical for data scientists. The modest difference may reflect the fact that the GRE exam only tests fundamental mathematical skills. The TOEFL score barely differs between the three performance groups; however, this may not be surprising since the mean values are quite high, indicating that most students have more than sufficient English language skills.

There is an obvious pattern with respect to the percentage of foreign nationals—the percentage of foreign nationals increases from 59.1% for the bottom 20% to 85.7% for the top 20%. This marked difference occurs even though we showed in Section 2.3 that the percentage of foreign nationals is relatively constant across the three admissions categories. It is worth mentioning that many of the foreign nationals completed their undergraduate education in the United States. The data also shows that a higher percentage of students in the top 20% previously earned a graduate degree. This may seem intuitive, but since these degrees are generally in very different disciplines, the relationship is not obvious. Such students will have demonstrated the prior ability to complete graduate work and perhaps the maturity associated with this is a significant factor. A graduate degree is considered quite favorably in the admissions process, and also enables a student to compensate for a low undergraduate GPA.

Students in the top 20% are less likely to be married than those in the bottom 20%, but the trend is not consistent through the middle 60%, so we tend not to place too much weight on these differences. The students in the top 20% are more likely to be female than those in the bottom 20% (35.7% versus 22.7%) and this suggests that there is a real gender difference. The explanation for these gender differences is not obvious, but at the undergraduate level we have observed that academically weak female students tend not to major in Computer Science due to the societal pressure that already discourages them from majoring in scientific and technical disciplines.

The next two features show that higher performing students tend to have more time since the granting of their last degree (about one more year), but are still approximately the same age. This could reflect the fact that students who immediately proceed from an undergraduate degree to the MSDS program have not thought as deeply about their desire to become a data scientist and hence may not be as committed. The school rank does not differ significantly between the performance categories, suggesting that the reputation of the prior school is not a key factor in student performance in the MSDS program. Finally, there is a very clear trend that the higher the GPA in the prior degree, the higher performing the student. This is perhaps the most obvious indicator of future achievement and the values support that: the prior GPA of those that are in the top 20% of the MSDS program is 3.53 versus 3.17 for those in the bottom 20%.

3. EXPERIMENT METHODOLOGY

This section describes the experiments related to predicting student academic performance in the MSDS program. Section 3.1 precisely defines the problem as a classification problem. Section 3.2 provides a brief description of the eight classification algorithms utilized in this study. The details concerning the design of the experiments are provided in Section 3.3.

3.1 Problem Formulation

We are primarily interested in identifying the applicants that will perform very well and will have GPAs within the top 20% of enrolled MSDS students, or will perform poorly and fall within the bottom 20%. The reason for this is that

we want to deny admission to those who we anticipate will perform in the bottom 20% and may want to provide merit-based aid to those we expect to perform in the top 20%. Note that this does not mean we only deny admittance to the bottom 20%, since admission will already be denied to those who do not meet our general admissions requirements (e.g., GPA above 3.0, TOEFL above 80, etc.). We therefore build two classification models: one that distinguishes the top 20% from the bottom 80% and one that distinguishes the bottom 20% from the top 80%. The minority class is always considered the positive class. The performance of these two models is described in Section 4.

3.2 Classification Algorithms

This section provides brief descriptions of the established machine learning algorithms that are employed in this study. A heterogeneous ensemble approach is also described.

3.2.1 Logistic Regression

Logistic Regression [12] is a type of generalized linear model (GLM) that studies the association between a categorical response variable Y and a set of independent (explanatory) variables $X = \{X_1, X_2, \dots, X_n\}$. In particular, the Y variable is first modeled as a linear function of X , and then the numerical predictions of Y are transformed into probability scores using a sigmoid function. In a binary classification task, the scores indicate a corresponding instance's likelihood of belonging to the positive class. Thus, a cutoff (usually 0.5) can be established as a decision boundary to further categorize the instances into the more likely class.

3.2.2 Support Vector Machines (SVM)

SVM [6] performs classification tasks by constructing a decision boundary in a multidimensional space that separates instances of different class labels. *SVM* strives to maximize the distance between the hyperplane and the data points of both classes. Maximizing the margin distance reinforces that future data points can be classified with more confidence. *SVM* is capable of transforming the data into a higher dimensional space using various kernel functions to enhance data separability. In this study linear *SVM* is used to facilitate risk factor analysis.

3.2.3 Decision Trees

A *Decision Tree* [16] model uses a tree structure to model the data in which each leaf node corresponds to a class label and attributes are represented as the internal nodes of the tree. Each branch represents a potential value of its parent node (i.e., an attribute). The major challenge in building a *Decision Tree* model is to choose the attribute for each node in each level. In our study we use the *Gini Index* as our criterion for attribute selection.

3.2.4 Random Forest

Random Forest [4] is a collection of decision trees, where each tree is trained with a subset of training instances and a subset of attributes. By pooling predictions from multiple decision trees, *Random Forest* reduces the variance of each individual tree and achieves a more robust and superior performance.

3.2.5 Neural Network

A *Neural Network* [9] is a computational model that is inspired by the way biological neural networks in the human brain process information. It consists of an input layer, one or more hidden layer(s), and one output layer. The adjacent layers are connected by transferring the values in one layer to a new set of values in the next layer with a set of weights and an activation function. “Training” is the process of adjusting the network weights using a back propagation algorithm to achieve the highest consistency (i.e., cross entropy) between the model outputs and the true class labels.

3.2.6 Naive Bayes

A *Bayes classifier* belongs to the family of probabilistic generative models. The algorithm differs from discriminative models in that, instead of finding a functional form, it models the probability distributions of the data. In a binary classification task, predictions are set to the larger of $P(y = i|X)$ where $i \in \{0, 1\}$ and $X = \{x_1, x_2, \dots, x_d\}$. A *Naive Bayes* classifier further assumes that features are independent of each other given the class, which simplifies the evaluation of $P(X|y=i)$ to $\prod_{j=1}^d p(x_j|y=i)$.

3.2.7 K-Nearest Neighbor (KNN)

KNN is an effective classification algorithm that does not require pre-training of a model. Classification decisions are based on a majority vote on k empirically observed instances that are most similar to the instance in question. The resemblance is typically measured by a distance metric such as Euclidean distance operated on the attributes describing the two instances.

3.2.8 Ensemble Learner L

In addition to individual machine learning algorithms, we explored ensemble techniques [7] to integrate information from different classifiers. Ensemble learning is a family of algorithms that seek to create a “strong” classifier based on a group of “weak” classifiers. In this context, “strong” and “weak” refer to how accurately the classifiers can predict the target variable. Ensemble learning has been proven to have improved and more robust performance than a single model. Specifically, multiple base classifiers are built for the original classification task with the training data. A meta-learner L is constructed by combining the outcomes from the base classifiers to improve predictive accuracy. In this study we combine the predictions from the base classifiers using an unweighted majority vote and our base learners consists of seven single models described in Sections 3.2.1 - 3.2.7.

3.3 Experiment Design

All experiments in this study utilize 10-fold cross validation. In addition to reporting overall predictive accuracy, the results in Section 4 and Table 3 report the performance on the positive/minority class via the sensitivity metric, which is also known as recall and true positive rate, and the performance on the majority/negative class via the specificity metric, which is also known as true negative rate. For both classification tasks, there is class imbalance since the ratio of the positive to negative class is approximately 1:4. Bagging is used to address this class imbalance; at training time five bags of balanced training data are created where each bag

consists of all minority-class examples and an equal number of randomly selected majority-class examples. The class for each test example is based on a majority vote of the five models built using the data from each bag.

The parameters of the models are selected experimentally using the training data using a grid search. Both the training and test accuracies are reported in Table 3. Specifically, for the SVM model, the trade-off parameter $C = 0.1$. For the KNN algorithms, the number of nearest neighbors $k = 3$. For the neural networks model, we used a 3-layer architecture with (128, 256, 512) nodes in identifying the bottom 20% of the students, and a two-layer architecture with (128, 256) nodes in identifying the top 20% of the students. For the rest of the algorithms, including the depth of the decision tree, the number of trees in the random forest, etc., we applied the default parameters provided by the Python scikit-learn package.

4. EXPERIMENT RESULTS

This section presents the results of the classification experiments. The accuracy results for identifying the top and bottom performing students are presented, as are the top predictors for identifying these two populations.

4.1 Analysis on Performance Measures

Table 3 presents all of the performance results for the two classification tasks. This analysis focuses exclusively on the performance on the test data. The results in the table show that *Random Forest* and the ensemble learner L achieve the two best overall predictive accuracy values for both classification tasks. For the tasking of identifying the bottom 20% of students, L achieved an 86% overall accuracy compared to 83% for random *Random Forest*. When these results are broken down into performance on the bottom 20% and the rest, L achieved results of 90% and 83%, respectively, versus 91% and 75% for *Random Forest*. It should be noted, however, that although *Decision Tree* has only the third best overall performance, it has the best performance at identifying the bottom 20% of the students (94% versus 91% for *Random Forest* and 90% for L). However, *Decision Tree* performs very poorly at classifying the remaining 80%, with a specificity of 65%.

For the classification task of identifying the top 20% of students, *Random Forest* delivered an overall accuracy of 86%, while L achieved an overall accuracy of 85%. When these results are broken down into performance on the top 20% and the rest, *Random Forest* achieved results of 94% and 79%, respectively, versus 92% and 79% for L . In this case *Decision Tree* again did very well when just evaluated on the minority class, with a performance of 94% for the top 20%, equalling the performance of *Random Forest* on this population. Note that since *Random Forest* is a collection of decision trees, it belongs to the family of *homogeneous* ensemble methods. Thus, we conclude that ensemble learners are the best machine learning models for the two classification tasks.

4.2 Analysis on Predictive Features

An additional motivation of our research is to identify the top predictors for the successful and struggling students.

Table 3: Performance Comparison Over Eight Models

Models	Bottom 20% vs. Rest						Top 20% vs. Rest					
	Test			Training			Test			Training		
	Bot20	Rest	Overall	Bot20	Rest	Overall	Top20	Rest	Overall	Bot20	Rest	Overall
SVM	0.74	0.62	0.68	0.85	0.69	0.77	0.68	0.54	0.61	0.75	0.58	0.67
Decision Tree	0.94	0.65	0.80	0.95	0.80	0.87	0.94	0.67	0.80	0.96	0.80	0.88
Random Forest	0.91	0.75	0.83	0.96	0.94	0.95	0.94	0.79	0.86	0.96	0.85	0.90
Logistic Regression	0.71	0.63	0.67	0.84	0.74	0.79	0.71	0.63	0.67	0.86	0.75	0.81
KNN	0.93	0.63	0.78	1.00	0.82	0.91	0.90	0.58	0.73	0.98	0.70	0.84
Naive Bayes	0.83	0.54	0.68	0.91	0.58	0.74	0.58	0.58	0.58	0.72	0.67	0.70
Neural Network	0.34	0.80	0.57	0.39	0.83	0.61	0.52	0.53	0.53	0.59	0.57	0.58
Ensemble (L)	0.90	0.83	0.86	0.96	0.92	0.94	0.92	0.79	0.85	0.96	0.87	0.91

Table 4: List of Top 10 Predictive Features in Identifying Bottom 20% of Students

Predictors of the Bottom 20% vs. Rest Models				
Rank	SVM	Logistic Regression	Random Forest	Decision Tree
1	Economics ¹	Economics ¹	GRE Verbal %	GRE Verbal %

1: School major

2: Country of last school

3: Citizenship code. Values include PR (permanent resident), FN (foreign), and US.

4: Last school degree.

The findings will help the admission committee to focus on more effective rubric measures and assign merit-based financial aid. Table 4 presents the top-10 predictors for the four classification algorithms: *Linear SVM*, *Logistic Regression*, *Random Forest*, and *Decision Trees*. These algorithms are selected because the rankings of predictive features are well-defined. In particular, for linear models the importance of a feature is proportional to the magnitude of its coefficients, while for tree-based models the ranking follows the order of the attributes used to partition the data (i.e., the attribute used to split the root node has highest rank).

Our first observation is that the *SVM* and *Logistic Regression* models rely heavily on applicants' background data including their undergraduate major, level of education, and country of origin. On the other hand, *Decision Trees* and *Random Forest* models utilize quantitative attributes such as GRE quantitative/verbal/writing scores, overall GPA, student age, and undergraduate school rankings. The superior performance of the *Random Forest* model compared to other standalone algorithms suggests quantitative measures are more reliable metrics in predicting a student's potential success in the MSDS program.

Our next analysis involves distinguishing the positive and negative predictors among the highly ranked predictive features. To this end, we resort to the magnitude of positive and negative weights provided by the linear classifiers (i.e., *SVM* and *Logistic Regression*) together with our first-hand experience in overseeing our MSDS program. Our findings suggest that students with an undergraduate major in Business, Economics, International Studies, Humanities, and Communications are poor candidates for an MSDS program, while applicants with Computer Science, Electrical Engineering, (Applied) Mathematics or Statistics backgrounds are more likely to succeed in the program. High GRE scores, Overall (undergraduate) GPA, and School Ranking, are positive indicators for success. We find these discoveries of important practical values because of the interdisciplinary nature of a data science program. Because data science programs attract students from diverse backgrounds, our studies suggest that a solid mathematics, computer science, or engineering background is essential for a student to be highly successful in an MSDS program.

5. CONCLUSION

Graduate admissions is a challenging task because it is generally controlled by faculty that have other responsibilities and priorities, and have limited training in the admissions process. The admissions process for a graduate data science program has even more challenges because it is interdisciplinary, most students do not have undergraduate backgrounds in data science, and the degree program has not existed long enough so that there is significant institutional knowledge about what applicants make the best (and worst) data science students. Thus this is an area that can benefit from data mining. The results in this paper show that mining a combination of admissions application data and student performance data can help to identify those students who are likely to do well, as well as those that are likely to struggle in their studies.

The results in this study demonstrate that our models can effectively identify both top students, who could then be offered the merit-based aid that is allocated to the MSDS program, and the bottom-performing students, who then could be denied entry into the program. The results show that our best-performing algorithms can achieve an accuracy of about 90% when identifying either the top or bottom performing students. We feel that these results are sufficiently strong that it is reasonable to take action based upon them.

The data analyses conducted in this study, as well as the examination of the features that are most important for some of the classification models, both provide valuable insight into the factors that influence success in the data science program. The key conclusions are summarized below. However, in viewing these, it is important to understand that these conclusions are based on the performance of enrolled students, so those students with weak backgrounds (e.g., very low GRE scores) will have already been excluded. Our analysis shows that the GRE quantitative score and, to a lesser extent, the GRE verbal score, do impact performance in the program, but only to a modest degree—perhaps to a lesser extent than we expected. The TOEFL score has almost no impact (partially due to the fact that all admitted students have satisfactory TOEFL scores). However, the GPA from the last degree, which is usually an undergraduate degree, has a very strong impact on performance in the program. The major associated with the last degree also plays a significant role, with computer science, mathematics, and engineering degrees positively impacting success in the program, while business, communications, economics, psychology, and humanities degrees negatively impacting performance. Students who are foreign nationals, female, hold prior graduate degrees, or who have been out of school for more than a year also tend to perform well.

There are many ways in which this study can be extended. The most straightforward is to utilize more data. Given that the current MSDS program is thriving, we expect in a few years there will be substantially more labelled data, as well as more unlabelled data since many students will either be rejected or will choose not to enroll. We believe that we can leverage this unlabelled data to improve the results via the use of semi-supervised learning algorithms. During this study, we tried to leverage the existing unlabelled data, but there simply was not enough to have a significant impact given the diversity of the applicant pool. We also tried to use our domain knowledge to form data subgroups to fine-tune the model. We hypothesize that students with different backgrounds warrant different treatment, but currently we have too little data and too many feature values to leverage this information. Exploring algorithms such as SVM+[17], which facilitates learning with heterogeneous data, can further improve the efficacy of our models. Finally, we are very interested in extending this work to other STEM graduate programs, including the MS in Cybersecurity and MS in Computer Science degree programs that currently reside in our department.

ABSTRACT

Response time has been used as an important predictor of student performance in various models. Much of this work is based on the hypothesis that if students respond to a problem step too quickly or too slowly, they are most likely to be unsuccessful in that step. However, something that is less explored is that students may cycle through different states within a single response time and the time spent in those states may have separate effects on students' performance. The core hypothesis of this work is that identifying the different states and estimating how much time is devoted to them in a single response time period will help us predict student performance more accurately. In this work, we decompose response time into meaningful subcategories that can be indicative of helpful or harmful cognitive states. We then show how a model that is using these subcategories as predictors instead of response time as a whole outperforms both a linear and a non-linear baseline model.

Keywords

Response time, student modeling, regression models, on-task and off-task behaviors

1. INTRODUCTION

Intelligent Tutoring Systems (ITS) help students learn a wide variety of skills from problem solving [23] to reading [22, 19]. To improve ITS designs, researchers often study students' learning patterns to identify their relationship to performance and target them for intervention. Within this context, response time has been widely used to predict student performance [39, 40] and to interpret cognitive and motivational states during ITS use [39, 3, 7].

Much of the research involving response time is based on

*These authors contributed equally to this work.

Zhila Aghajari, Deniz Sonmez Unal, Mesut Erhan Unal, Ligia Gómez and Erin Walker "Decomposition of Response Time to Give Better Predictions of Children's Reading Comprehension" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 334 - 341

the hypothesis that the relationship between response time and student performance is non-linear [9]. Fast or slow response times may be indicative of both helpful and harmful cognitive states. For example, a fast response time could be a result of either mastery of a skill or guessing. Likewise, a long response time could be because of struggling or being off-task. Contextual information surrounding response time is often used in identifying the correct cognitive or motivational states. For example, a long response time after reading a bug or a hint message can be linked to reflection [32], whereas a short response time after such actions can be a sign of gaming the system [4]. Thus, previous literature has focused on identifying students' cognitive states based on sequences of actions and the time spent between them [4, 2, 7, 5]. However, students may go through different cognitive states even within a time period between consecutive actions [32]. Despite a large body of research dedicated to studying students' cognitive states, little is known about the different states a student might be in during a single response time and how time spent in those states would affect learning.

We hypothesize that response time can be divided into subcategories that can be indicative of some helpful and harmful cognitive states, and that identifying time spent on these states within one response time can improve student performance prediction. In our previous work [35], we divided response times during a reading comprehension task into two: reading and thinking time. Results of a piecewise regression model revealed that thinking time could include four states: gaming, productive thinking, wheel spinning, and mind wandering. With the insight from these results, we further investigate the different states that could occur in one response time. We compare a model that is based on decomposition of response time to a linear baseline model which only uses average response time, and also to a non-linear baseline (a piecewise regression). By decomposing the response time, we show that students can go through multiple cognitive states in between log events. We also show that by identifying how much time is devoted to these states, we can improve the predictive models of student performance.

2. RELATED WORK

2.1 Cognitive and Motivational States

Within this section we review the cognitive states that are related to productive thinking, gaming the system, and unproductive thinking. We extract these states from the broader research literature, although it should be noted that these states were also identified by teachers as important [13].

We gather learning events that are associated with robust learning under **productive thinking** behaviors. [17] divided these events into three categories: understanding and sense-making processes, induction and refinement processes, memory and fluency-related processes. Some example behaviors that fall under understanding and sense-making processes and induction and refinement processes that could be relevant in a reading domain are self-explanation and self-reflection. These behaviors are shown to be positively related to learning [32, 8].

Gaming the system is an undesirable cognitive state wherein students try to reach the correct answers and advance in the lesson by systematically misusing the features of the system [3]. It is linked to short response times and rapid actions [3]. [29] divides gaming into two main types: systematic guessing and help abuse. Systematic guessing could be inferred from short response times between step attempts [12, 28, 2], entering the same answer in multiple contexts, and entering similar answers [29]. Help abuse was defined as searching for bottom-out hints, asking for help without any reflection on the help, and entering multiple incorrect answers despite receiving help.

Within **unproductive thinking** states, we review wheel spinning and mind wandering. **Wheel spinning** occurs when the student makes an effort but does not succeed. It is linked to long response times and many help requests. [7] illustrates that if students need help solving the first twenty problems they are in wheel spinning phase, and presenting them with more problems will not be helpful. [5] showed wheel spinning is negatively correlated with flow, positively correlated with gaming and confusion, and not correlated with boredom. **Mind wandering** occurs when students involuntarily shift their attention to task-unrelated thoughts [15, 14, 34], and is associated with distraction or boredom. This cognitive state occurs 20-40% of the time during reading [30] and causes students to fail in gaining reading comprehension skills [33, 36]. As mind wandering occurs involuntarily, it is very difficult to measure, and it is often measured using self-reported approaches [24].

2.2 Response Time in Student Modeling

Response time has been widely used in different kinds of student models, and can improve the accuracy of those models [39, 20]. For example, [4] presents a model that uses response time to detect shallow learning, and [11] predicts student performance in transfer learning using response time. [6] developed an item response theory (IRT) model to show an overall level of students engagement by analyzing response times, problem difficulty, and correctness of responses. [16] also presents an IRT-based model to estimate student proficiency and motivation level where motivation was measured based on time spent between actions and a short response time was an indicator of unmotivated behavior.

In this paper, we are inspired by work that centers response

time as a non-linear predictor of students' performance. [9] suggests that the relationship between time and student success is not linear, and there is an ideal range of time for students to respond to a problem. In [10], they further support this non-linear relationship by showing that including time as a quadratic predictor instead of linear yields to a better prediction of students' performance. These studies support the intuition that accounting for the activities in different ranges of response time can give a better prediction of student performance.

Other efforts have shown success in estimating time spent on the activities that occur within a single response time. These efforts involved decomposing response time. [32] presented a model that predicts student performance relying on estimation of activities that cannot be directly observed from the log data such as thinking about hints, entering an answer, and reflecting on the hints. The preliminary results of our previous work that decomposes response times in a reading comprehension domain also revealed that students may go through multiple cognitive states during a single response time period [35].

In this work, we aim to show that identifying time spent on different cognitive states within the response time will provide better predictions of student performance.

3. CORPUS AND MEASURES

The datasets used in our work are log data collected during two studies with an iPad application called EMBRACE [38]. EMBRACE is designed to help young dual-language learners improve their reading comprehension in English. The students read interactive story books divided into chapters and they answer 3 to 9 multiple choice questions about the text at the end of each chapter. Books consisted either of narrative stories or of informational texts. Students see the text they should read in a box and they press a button labeled "Next" at the bottom of the screen to move from one sentence to another. They also see images representing what is depicted by the text.

In the full versions of EMBRACE, students are asked to either imagine the highlighted sentences or move the images on the screen to enact these sentences. They can get feedback based on how they are moving the images. Some features that are in the full versions of EMBRACE are not provided in the control version. Students still see the images in this version as well as the highlighted sentences, however, the only actions that they can perform are tapping on words to hear their pronunciations, and pressing the "Next" button to move to the next sentence. In this work, we are particularly interested in the control version as it gives us a more restricted set of student actions, which better enables us to focus on the role response time plays in reading comprehension. In the control version, we use the following measures:

1. **Student performance:** The proportion of correctly answered questions at the end of the chapters.
2. **Response time:** The time spent between when the sentence is first loaded and when the student presses the 'Next' button to proceed to the next sentence.
3. **Help requests:** The frequency of tapping on an underlined word to hear its pronunciation in a sentence.

Response time initially includes time spent on gaming, reading and thinking.

Step 1. Calculating gaming time and subtracting it from response time.

Step 2. Calculating reading time and subtracting it from remaining portion of response time.

Step 3. Distinguishing between productive and unproductive thinking times.

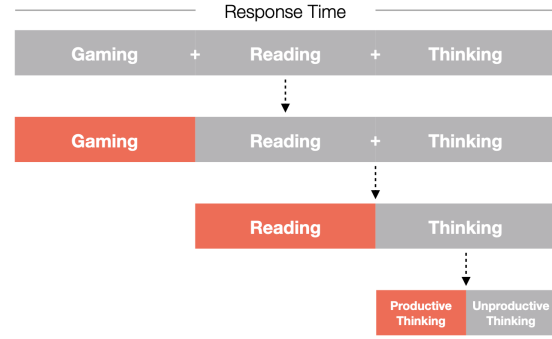

Figure 1: The protocol of designing productive vs. unproductive thinking portions in students learning.

4. **Frequency of gaming:** The “Next” button is disabled for 1 to 3 seconds depending on the length of the sentence to encourage the students to read the sentence completely. However, students might try to skip the current sentence and press this button while it is disabled. Frequency of this behavior within a sentence is our indicator of gaming since systematic and rapid actions to advance in the curriculum has been identified as gaming in previous research [3]. Note that this metric is not available in the second dataset.
5. **Decoding ability:** Decoding is defined as the ability to correctly pronounce written words. Our decoding measure is the student’s score on the decoding part of Qualitative Reading Inventory (QRI) [18] that is in range [0, 40].
6. **Sentence difficulty:** We used the Flesch-Kincaid readability grade level (FK) [21] to measure sentence difficulty. It is based on number of words in the sentence, and syllables in words. This measure represents the grade level required to understand a certain text. The difficulty of each chapter is calculated based on the average difficulty of the sentences in the chapter. FK is often used for long texts rather than single sentences. To confirm this measure is also appropriate for computing sentence level difficulty, we also computed chapter difficulty by applying FK on complete chapter texts. We did not observe a noticeable difference between computing sentence level difficulties per chapter ($M = 4.81$, $SD = 1.39$) and applying FK on complete chapter texts ($M = 4.64$, $SD = 1.35$) as $RMSE = .37$.

In our datasets, data points are distinct student-chapter pairs as student performance can only be calculated in chapter level. The first dataset includes 22 students who are native Spanish speakers from second to fourth grade with mean QRI score 34.71 ($SD = 5.19$). One student is excluded from the dataset due to having scored less than 50% on the QRI test, and thus being unable to effectively use the application. We also excluded the first chapters of the books that were read out loud to the student by the application. Finally, some of the student-chapter pairs are excluded from the dataset due to logging errors such as unrealistic response times or not completing the chapter. In total, we had data from 21 students, and 716 distinct student-chapter pairs. The mean number of book chapters per student is

Table 1: Descriptive statistics of time (in seconds) subcategories across student-chapter pairs in the first dataset (Spanish)

Measurements	Mean	SD	Min	Max
Reading Time	6.04	1.67	1.11	11.44
Productive Thinking	2.18	1.72	0	7.84
Unproductive Thinking	1.68	4.01	0	39.47
Gaming Time	0.21	0.44	0	5.36
Time Spent on Help	0.15	0.09	0.07	0.33
Time Spent on Sentence	10.12	6.02	2.75	51.5

Table 2: Descriptive statistics of time (in seconds) subcategories across student-chapter pairs in the second dataset (Mandarin)

Measurements	Mean	SD	Min	Max
Reading Time	4.40	0.65	2.67	6.12
Productive Thinking	2.68	1.07	0.01	4.09
Unproductive Thinking	1.45	3.08	0	27.79
Gaming Time	0.08	0.38	0	4.09
Time Spent on Help	0.84	0.60	0.06	3.61
Time Spent on Sentence	9.17	4.29	2.81	39.56

34.09 ($SD = 2.3$) with mean sentence difficulty 4.82 ($SD = 2.84$) across 7 story books.

In the second dataset, collected from an earlier experiment, we had 24 native Mandarin speaker students from seventh to ninth grade with mean QRI score 37.42 ($SD = 1.79$). Only one student-chapter pair was excluded from the dataset as the student in that pair did not complete the assessment task for the chapter. In this dataset we had 479 distinct student-chapter pairs. The mean number of book chapters per student is 19.95 ($SD = 0.20$) with mean sentence difficulty 4.14 ($SD = 1.06$) across 4 story books.

4. RESPONSE TIME DECOMPOSITION

Figure 1 visualizes how we decompose response time at a high level. In the following subsections we describe how each time subcategory was computed in detail. The descriptive statistics of the time subcategories for the datasets are given in Tables 1 and 2.

4.1 Time Spent on Gaming

For each sentence, if the student never pressed “Next” when it was disabled, the gaming time on that sentence is 0. Otherwise, we first calculate how long the student waited after the last time they pressed “Next” when it was disabled until they actually passed the sentence. We calculated gaming time by subtracting this waiting time from total time spent on sentence. A student who waited for a long time to pass the sentence after pressing “Next” when it was disabled will have a low gaming time estimate. Note that, in the second dataset, since our gaming indicator was not available, we did not include gaming time in our analyses.

4.2 Time Spent on Reading

We first estimated how many words students should read per minute based on their grade according to [25]. For example, if a student is in third grade, they should be able to read between 120 to 170 words per minute. To give a more specific estimate for reading rate, instead of using only the student’s grade, we include their ability in decoding English words and sentence difficulty, as students with a higher decoding ability may read more words. Similarly, in more difficult texts, students may read fewer words per minute. We first divide the normalized decoding score by the normalized sentence difficulty for each student and sentence pair. Let $[a, b]$ be the interval representing the possible values of this measure. We create another interval $[c, d]$, by getting the possible values of how many words students should read per minute within our students’ grade levels from [25]. We simply map interval $[a, b]$ on interval $[c, d]$ using the linear mapping formula below:

$$f(x) = c + ((d - c)/(b - a)) * (x - a) \quad (1)$$

Here, x is one specific decoding/difficulty score for a student-sentence pair and $f(x)$ will give an estimate for how many words this student should read adjusted by the student’s decoding ability and the difficulty of the sentence. Then, we simply calculated the time spent on reading for each sentence based on the student’s reading rate and the word count in the sentence. For example, if a student is estimated to read 120 words per minute, their reading time estimate for a 6-word sentence is 3 seconds.

$$T_{\text{read}_{u,s}} = \frac{s_w}{u_{\text{wpm}_s}} * 60s \quad (2)$$

Here $T_{\text{read}_{u,s}}$ denotes the time estimate for student u to read sentence s , s_w denotes the number of words in sentence s and u_{wpm_s} denotes the rough estimate of the reading rate for student u while reading sentence s .

4.3 Time Spent on Help Requests

We computed the exact time it takes to play the help audios. Then we computed the time spent on help requests by multiplying the time it takes to play the tapped words by two as each word is played twice.

4.4 Time Spent on Thinking

Finally, we calculate the thinking time by simply subtracting gaming time, reading time and time spent on help requests from total time spent on one sentence.

$$T_{\text{think}_{u,s}} = T_{\text{total}_{u,s}} - (T_{\text{game}_{u,s}} + T_{\text{read}_{u,s}} + T_{\text{help}_{u,s}}) \quad (3)$$

Following this procedure, thinking time was estimated to be negative for 34% of the data points as the reading time

Figure 2: Example student-level thresholds for a high decoding (left) and a low decoding student (right).

estimate was higher than the total time spent on sentence. In that case, we simply adjust reading time estimate so that the time spent on sentence would be equal to reading time, and thinking time would be assigned to 0, which means that the time spent on sentence was devoted to reading and/or gaming. Even though zeroing-out negative thinking times seems to remove the variance that could be indicative of student performance, we did not observe any difference in terms of model performance. Moreover, doing so resulted in thinking time estimates becoming more interpretable.

4.5 Distinguishing Between Productive and Unproductive Thinking Time

To distinguish between productive and unproductive thinking, we use a data-driven method to find a threshold in thinking time for a student and chapter where spending more time on thinking after passing that threshold will be unhelpful. We first estimate that threshold at the student level and then similarly at the chapter level. We then combine the two thresholds to estimate one threshold for each student-chapter pair.

To find student level thresholds, using the `segmented` function in R [26, 27], we fit a separate piecewise regression model with our performance measure as the outcome and the mean time spent on thinking as the predictor for each student ($R^2 = 0.24$). There will be one breakpoint in thinking time for each student which will be independent of the chapter. Similarly, to estimate the thresholds at the chapter level, we fit one piecewise regression model with the performance measure as the outcome and the mean time spent on thinking as the predictor for each chapter (across all students) ($R^2 = 0.23$). The breakpoints represent the thresholds distinguishing between productive and unproductive thinking times for chapters. Figure 2 shows example thresholds returned from the piecewise regression models for a high decoding and a low decoding student, and Figure 3 shows example thresholds for an easy and a difficult chapter. High and low decoding students and easy and difficult chapters were decided based on median splits.

Although the separate thresholds we found are reasonable estimates, we do not use them directly when deriving the time spent on productive thinking, for two reasons. First, the threshold between productive and unproductive thinking time should be adjusted to both student and chapter characteristics in the same way that we adjusted time spent

Figure 3: Example chapter-level thresholds for an easy chapter (left) and a difficult chapter (right).

Figure 4: The relationship between decoding score and estimated student-level thresholds (left), and chapter difficulty and estimated chapter-level thresholds (right).

on reading. Second, we estimated these points by building a model which predicts the student performance, the variable that we would like to predict. Time spent on productive and unproductive thinking will be used as predictors in the model that we propose in this work. While extracting these features, leaking information from our outcome measure may cause overfitting in the final model. Therefore, we combine the thresholds found from separate regression equations. We build two separate linear regression models to predict the ‘true’ student and chapter level thresholds. Then we combine the two equations by taking their weighted average. This allows us to have one threshold estimate for an arbitrary student-chapter pair based on the decoding ability of the student and the difficulty of the chapter.

Figure 4 shows the relationship between QRI and ‘true’ student-level thresholds, and the relationship between chapter difficulty and ‘true’ chapter level thresholds. As seen in the figure, the estimated student-level thresholds are negatively correlated with decoding ability. This indicates that segregates productive and unproductive thinking regions occurs earlier for the students who scored better in the decoding test. The same figure also shows that chapter-level thresholds and chapter difficulties are far less correlated, which suggests that in estimating a threshold based on both student and chapter characteristics, the student characteristic (decoding score) is more important than the chapter characteristic (difficulty).

To combine these thresholds, we first find the equation for chapter difficulty and thinking time thresholds.

$$\lambda_{\text{chapter}} = \hat{B}_0 + \hat{B}_1 * \text{DIFF}_{\text{chapter}} \quad (4)$$

Here $\text{DIFF}_{\text{chapter}}$ denotes the chapter difficulty, and \hat{B}_1 and \hat{B}_0 are the estimated slope and y -intercept of the linear equation respectively. Similarly, we learn an equation for thinking time threshold in student level as follows:

$$\lambda_{\text{student}} = \hat{C}_0 + \hat{C}_1 * \text{QRI}_{\text{student}} \quad (5)$$

where $\text{QRI}_{\text{student}}$ denotes the student’s decoding score, and \hat{C}_1 and \hat{C}_0 denote the estimated slope and y -intercept of this linear equation respectively. We combine these two separate thresholds by taking the weighted average of them. We weigh the equations by the correlation coefficient between the QRI score and the estimated student level thresholds (x), and the correlation coefficient between chapter difficulty and the estimated chapter level thresholds (y). We find the combined threshold as follows:

$$\lambda_{\text{combined}} = \frac{x * \lambda_{\text{chapter}} + y * \lambda_{\text{student}}}{|x| + |y|} \quad (6)$$

where $x = 0.05$ and $y = -0.39$. Using this equation, we have one estimate for thinking time threshold for a given student and chapter based on both decoding ability of the student and chapter difficulty.

Finally, productive thinking time is defined as time spent on thinking before this threshold. If the time spent on thinking is less than this threshold for a given student and chapter pair, all thinking was productive and time spent on unproductive thinking is 0. If the time spent on thinking is larger than the threshold, time spent on thinking until the threshold will be counted as productive thinking time and any time beyond the threshold will be counted as unproductive thinking time.

5. PREDICTING COMPREHENSION

The core hypothesis in our work is that dividing response time into subcategories in a way that could be indicative of some helpful and harmful cognitive states will improve predictive models of student performance. To test this hypothesis, we compared the proposed linear model (Decomposed RT) to two baselines: one that uses response time as whole (Baseline 1), and another that uses response time as a non-linear predictor (Baseline 2) to show that we are not simply accounting for non-linearity in response time but we show identifying the states within response time will help us predict comprehension more accurately. We report AIC [1] and BIC [31] to show the improvement in the model is not because of the increased number of predictors. Table 3 summarizes the feature sets we used in the 3 models we compare. We performed a cross-validation at the student level within a scheme for 50 iterations in which each time we left out a unique student pair from the whole procedure (decomposition of response time and training the models) and used their data for testing.

Table 4 shows the average RMSE, R^2 , AIC and BIC values of the 50 iterations. For both datasets, we randomly flip the sign of the difference between paired model outcomes to conduct a paired-sample permutation test [37] to compare the mean of differences in evaluation metrics between our model and each baseline. We performed 1000 permutation trials in total. For the first dataset, we found significant improvements against both baselines in RMSE ($p < 0.005$), in AIC ($p < 0.001$), and in BIC ($p < 0.001$).

Table 3: Feature sets used in the models: Decomposed RT, Baseline 1, and Baseline 2. † indicates being a significant predictor ($p < 0.05$) of student performance in more than 80% of the folds.

Decomposed RT (Linear regression)	Baseline 1 (Linear regression)	Baseline 2 (Piecewise regression)
1. Frequency of gaming ¹ 2. Frequency of help requests 3. Chapter difficulty † 4. Student decoding score † 5. Time spent on reading † 6. Time spent on gaming ¹ 7. Time spent on productive thinking † 8. Time spent on unproductive thinking	1. Frequency of gaming ¹ † 2. Frequency of help requests † 3. Chapter difficulty † 4. Student decoding score † 5. Time spent on sentence †	1. Frequency of gaming ¹ † 2. Frequency of help requests 3. Chapter difficulty † 4. Student decoding score † 5. Time spent on sentence † (<i>as the non-linear parameter</i>)

Table 4: Comparison of evaluation metrics for proposed model and baselines on the first (Spanish) and second (Mandarin) dataset

	Model	RMSE	R^2	AIC	BIC
First Dataset	Decomposed RT (Linear regression)	.267 (.027)	.220 (.013)	80.242 (14.441)	124.988 (14.446)
	Baseline 1 (Linear regression)	.275 (.034)	.160 (.013)	122.399 (16.785)	153.721 (16.796)
	Baseline 2 (Piecewise regression)	.273 (.031)	.193 (.012)	100.868 (16.259)	141.139 (16.276)
Second Dataset	Decomposed RT (Linear regression)	.268 (.034)	.131 (.014)	58.350 (10.521)	91.027 (10.521)
	Baseline 1 (Linear regression)	.274 (.034)	.093 (.015)	73.090 (10.301)	97.599 (10.301)
	Baseline 2 (Piecewise regression)	.271 (.033)	.133 (.012)	57.508 (10.067)	90.185 (10.068)

For the second dataset, while decomposing response time, we made two adjustments. Firstly, since the students in this dataset were older (from 7th to 9th grade), their reading rates were adjusted for their grade level when calculating reading time. Secondly, the version of EMBRACE that was used to collect this data was not tracking when the students were pressing the “Next” button when it was disabled. Therefore, we discarded gaming time from our model. The remaining subcategories are calculated the same way as we did in the first dataset. The improvement in RMSE was significant against both Baseline 1 ($p < 0.001$) and Baseline 2 ($p < 0.005$). The improvement in AIC and BIC was significant against Baseline 1 ($p < 0.001$) while Baseline 2 was significantly better than Decomposed RT ($p < 0.05$).

Overall, Decomposed RT outperformed both baselines both in prediction error and the model fit criteria in the first dataset. However in the second dataset, although we see an improvement in prediction errors in favor of Decomposed RT, Baseline 2 had significantly better AIC and BIC values than Decomposed RT.

6. CONCLUSION

Within this paper, we proposed a new methodology to decompose response time so that time spent on gaming the system, productive thinking, and unproductive thinking states within a single response time can be accounted. Results showed that, using the time spent on these states as separate predictors rather than using response time as a whole gave better predictions of student performance. Comparison against another baseline that employs response time as a non-linear predictor also revealed that the improvement was not due to addressing the non-linearity in response time,

¹This measure is available only in the first dataset (Spanish).

and using the decomposition of response time to explain how much time was spent on different cognitive states indeed yielded better predictions. Moreover, comparison of AIC and BIC values supported that the improvement in the predictions were not due to introducing more predictors. However, we could not observe the same results for AIC and BIC between the proposed model and the non-linear baseline on the Mandarin dataset. A possible explanation is that we were not able to estimate the time spent on gaming in this dataset, thus time estimates for the other states were not as accurate as in the first dataset.

There are several other limitations of the work that need to be noted. Firstly, our estimation of reading time might not be the most accurate as there may be more factors influencing reading time than we addressed such as frequency of words and familiarity with the topic. Secondly, our model does not distinguish between the unproductive thinking behaviors (mind wandering and wheel-spinning) in its current stage. We plan to further explore how we can capture these different kinds of unproductive thinking.

In conclusion, we proposed a new method to use response time as a predictor in student modeling. The results show a promising improvement in predictive models of student performance when response time is decomposed into subcategories that can be indicative of the possible cognitive states students engage in. Future work should further assess this method’s generalizability to different student profiles and different domains.

Whose Truth is the “Ground Truth”? College Admissions Essays and Bias in Word Vector Evaluation Methods

Stanford University
ajalvero@stanford.edu

ABSTRACT

Word vectors are widely used as input features in natural language processing (NLP) tasks. Researchers have found that word vectors often encode the biases of society, and steps have been taken towards debiasing the vectors themselves. However, little has been said about the fairness of the methods used to evaluate the quality of vectors. Analogical and word similarity tasks are commonplace, but both rely on purportedly ground truth statements about the semantic relationships between words (e.g. “man is to woman as king is to queen”). These analogies look reasonable when only taking into account the literal meanings of words, but two issues arise: (1) people don’t always use words in a literal sense, and (2) the same word may be used differently by different groups of people. In this paper, we split a dataset of over 800,000 college admissions essays into quartiles based on reported household income (RHI) and train sets of word vectors on each quartile. We then test these sets of vectors on common intrinsic evaluation tasks. We find that vectors trained on the essays of higher income students encode more of each task’s target semantic relationships than vectors trained on the essays of lower income students. These results hold even when controlling for word frequency. We conclude that the tasks themselves are biased towards the writing of higher income students, and we challenge the notion that there exist ground truth semantic relationships that word vectors must encode in order to be useful.

1. INTRODUCTION

Text analysis has grown into an important topic, with researchers from education, industry, social sciences, humanities, and traditional STEM programs harnessing large amounts of textual data that is widely available and relatively easy to access. Text data is usually very sparse (as most words do not appear in most documents) and difficult to use as input for mathematical models. This has given rise to a variety of vectorization methods that include simple word counting, statistical methods like TF-IDF, and neural methods used to generate dense representations called word vectors. Word

vectors have been shown to produce high quality results in a variety of machine learning (ML) and natural language processing (NLP) tasks, but this potentially comes with a social cost. Research has shown that word vectors propagate the gender and racial biases found in society [19, 7, 10]. However, little has been said about the fairness of the methods that we use to evaluate vectors.

After a set of word vectors has been trained on a corpus, researchers and engineers want to evaluate the quality of the vectors. As a result, a standard set of word vector evaluation tasks [41] has been developed in order to measure how useful and generalizable a given set of vectors is. When researchers propose new methods for training word vectors, they demonstrate the performance of their methods by evaluating the resulting vectors on these tasks. Furthermore, when NLP systems are built, vectors that perform well on these tasks are most likely to be chosen.

Word vector evaluation tasks are either intrinsic (performed directly on the vectors) or extrinsic (performed by using the vectors as inputs for a downstream task). Intrinsic evaluation is popular because it is very inexpensive, but it relies on having some secondary notion of what makes vectors useful. The most popular methods assume that there are “ground truth” semantic relationships that a set of word vectors must encode in order to be useful. However, due to sociolinguistic variation, not all language communities share the same semantic relationships [4]. As a result, in order for these tasks to be fair, they need to use semantic relationships that are universal: if semantic relationship R holds in the language patterns of group G but not group H , then the usage of R in an intrinsic evaluation task will bias researchers towards sets of vectors that model group G ’s language usage better than group H ’s. We use this framework to evaluate the fairness of two popular forms of intrinsic evaluation, analogical tasks and word similarity tasks.

When working with large text corpora, especially in educational contexts, it is important to consider the role of sociolinguistic variation [27]. In particular, students have been punished and targeted for their language practices if they are perceived to be different from the “mainstream” [38, 42]. Understanding how social variation in language affects word vectors is necessary in order to tackle two critical issues. The first is the question, “whose language is being modeled?” Word vectors are meant to capture something about the semantics of each word. If theories of sociolinguistic variation

Noah Arthurs and Aj Alvero “Whose Truth is the “Ground Truth”? College Admissions Essays and Bias in Word Vector Evaluation Methods” In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 342 - 349

tell us that people from different groups use language in different ways, then we must wonder if standard word vector sets like GloVe [35] are serving everyone equally. Second, we must ask, “how does fairness change across contexts?” In NLP, word vectors that perform well on intrinsic evaluations are used across many different contexts. However, if fairness involves taking sociolinguistic variation into account, it may not be the case that vectors that are unbiased in one context are biased in another.

Educational agencies and institutions are also increasingly relying on algorithms to help with decision-making processes. College admissions offices have been pushed to use AI [3] but have legal and ethical mandates to ensure process fairness for applicants based on their demographics and/or protected statuses, like race, gender, and religion. As the number of college applications rise and the need to hire reviewers increases, applicant admissions essays are a likely candidate for some form of automation. Research on the essays encode some degree of applicant gender and social class [2], making careful adoption of AI necessary. If sociolinguistic variation is not taken into account, algorithms have a high chance of reproducing social inequalities.

We address these issues by analyzing a corpus of over 800,000 college admissions essays (CAE) submitted to a selective, multi-campus university system. In addition to the essays, we have a variety of author metadata, including each student’s reported household income (RHI). We split the dataset into quartiles by RHI and train one set of word vectors from scratch on each quartile. After training, we find that on both the analogy and similarity tasks, the vectors trained on the writing of higher income students encode more of the target semantic relationships than vectors trained on the writing of lower income students. This indicates that the tasks can be biased against the writing of lower income students.

Our contributions are:

- to challenge the paradigm of “ground truth” labels for intrinsic evaluation by starting with the premise that language distributions vary along demographic characteristics.
- to provide a method for auditing the fairness/bias of an evaluation task, complementing existing methods for auditing the fairness/bias of word vectors themselves.
- to contribute to the educational scholarship of higher education by characterizing sociolinguistic variation in college admissions essays using established AI techniques.

2. BACKGROUND

2.1 Word Vectors

In NLP, word vectors (or word embeddings) are the standard way to translate words into input features for machine learning models. Popular word vector training algorithms like word2vec [30] and GloVe [35] are based on the distributional hypothesis, the idea that a word’s meaning is encoded in its co-occurrences with other words. In particular, word2vec tries to learn features which can be used to predict

Figure 1: Illustration of simple vector operations modeling semantic (left) and syntactic (right) relationships in vector space from [32]

a word from its context (or vice versa), and GloVe trains directly from a co-occurrence matrix. Both models take in large corpora of texts and create a dense representation of every word, usually in 100- to 300-dimensional space.

2.2 Word Vector Evaluation

As described above, vectors can be evaluated intrinsically or extrinsically. Intrinsic evaluation, which is the focus of this study, involves directly examining the relationships between vectors. Intrinsic evaluation has the advantage of being much faster and more lightweight, but it comes with two downsides. The first is that intrinsic tasks do not resemble the use cases of word vectors as much as extrinsic tasks do. The second is that intrinsic tasks rely on “ground truth” human judgments about what the relationships between vectors *should* be.

The word analogy task is based on the idea that analogical relationships between words (e.g. “man is to woman as king is to queen”) should be encoded in word vectors as parallelograms (i.e. the vector that connects “man” to “woman” would be the same as the one that connects “king” to “queen”). Mathematically, this means that:

$$v_{\text{queen}} - v_{\text{woman}} \approx v_{\text{king}} - v_{\text{man}}$$

This kind of relationship has been found to hold for both for semantic (meaning-based) and syntactic (grammar-based) relationships (left and right sides of figure 1). The idea for the analogy task dates back to the 1990’s [17], but it was not proposed as a word vector evaluation technique until 2013 [31, 30]. Since then, it is common practice to compare sets of vectors on their ability to “solve” word analogies.

Word similarity is based on the idea that similar words (i.e. words that are used in similar contexts) should have similar word vectors. The word similarity task starts with a list of word pairs and involves finding the correlation between ground truth similarities between the words in each pair and the similarities between their corresponding vectors. The similarity between two vectors is in practice measured by taking their cosine similarity. The cosine similarity of two vectors \vec{a} and \vec{b} is defined as:

$$\frac{\vec{a} \cdot \vec{b}}{\|\vec{a}\|_2 \|\vec{b}\|_2}$$

which is equal to 0 if \vec{a} and \vec{b} are orthogonal, 1 if they are in the same direction, or (most of the time) something in between. The ground truth similarities, on the other hand, rely on human judgment. This task remains largely unchanged since its first iteration in 1965, when Rubenstein and Goode-nough [39] set out to test the distributional hypothesis. The big difference is that modern datasets for this task starting in 2002 with WS-353 [18] involve larger numbers of word pairs.

Both of these tasks require “ground truth” labels of some sort. The analogy task requires a list of analogies that the vectors are being tested for, while the similarity task requires ratings of the similarities between many pairs of words. These labels are problematic for two reasons. First, it has been pointed out that the labels for these tasks do not take into account the fact that words can take on many different meanings depending on context (polysemy). Second, word use and semantic intent vary along social dimensions, meaning that labels may reflect the language use of some groups better than others, thus creating bias. This second issue is the focus of our study.

2.3 Word Vector Critiques

It has been found that word vectors encode the biases present in their training data [7], and word vectors have been used to quantify the biases that exists in society [19]. Two methods have emerged for reducing bias in word embeddings: we can change our training process in order to penalize biased vectors [7], or we can identify and remove the training documents that are the source of the most bias [8].

Intrinsic evaluation methods have also fallen under scrutiny. Both the analogy task [14, 37] and the similarity task [16] have been criticized for relying on the fuzzy relationship between word similarity and vector similarity, and for not taking polysemy into account. Lastly, both tasks have been found to be poor predictors of extrinsic performance [11].

Although there have been numerous critiques of the bias encoded in word vectors and numerous critiques of intrinsic evaluation tasks, little has been said about whether or not intrinsic evaluation is biased in theory or practice. This study answers that question by identifying whether the “ground truth” semantic relationships prescribed by intrinsic evaluation tasks are shared by students of all income levels.

2.4 Sociolinguistic Variation

Language variation across spatial, demographic, and temporal dimensions is the bedrock theory behind sociolinguistics. Applied research in sociolinguistics often seeks to ameliorate systems and processes mediated through language, especially law [23] and education [36]. Relevant to this study, Bamman et al. showed significant regional variation in cosine similarity of word vectors for common words, such as “wicked” and “city” [4]. Sociolinguists are using computational methods to investigate language variation [33], but a general integration of sociolinguistics into NLP could help researchers identify and address biases.

A more equitable educational data science using text should therefore consider linguistic variation at the forefront of analysis. ML models and systems that do not account for this

risk classifying everyday language practices as hate speech, as was found to be the case with tweets written by AAVE users [40, 12]. Large datasets with student level metadata, like the data analyzed in this paper, will become increasingly common in education. Even basic sociolinguistic principles could help researchers address linguistic variation, use variation as a dependent variable, or explain how and why certain data correlates along various social dimensions to address the complicated relationship with student characteristics and language.

2.5 Household Income and College Admissions

Research on college admissions consistently shows that the college admissions process is easier for students from high income households. Studies have shown that standardized testing is strongly correlated with household income and other proxies for wealth [13], especially for black and white students. Other elements of the college application, such as financial aid forms [6] and the steps of the entire application process [26] are also more easily navigated by wealthy families than students from lower socioeconomic backgrounds. Family wealth is itself reflective of many racial and gender inequalities in the US [24].

The college admissions essay (CAE), has faced less scrutiny than standardized testing but some research has shown relationships to student identity and essay content. Using a corpus of CAE written by applicants in Britain, Jones [22] found that students from higher social classes wrote longer essays, had fewer spelling and grammatical errors, and tended to invoke markers of their higher social standing, such as the name of their elite school. Research by Kirkland & Hansen [25] found similar differences along income in diversity statement essays. They found that students from different racial backgrounds but similar socioeconomic levels wrote similar essays. Other studies have tested writing interventions with lower income students to teach them the genre of the CAE [15]. They found when students from a low income high school were explicitly trained on what they should include in their CAE, the average score of their essays on a rubric-based rating was higher than students that did not receive the intervention.

As universities move towards test optional admissions, fair analysis of CAE will become even more critical. If student backgrounds are not explicitly considered when using ML on CAE, new forms and abstractions of bias could be introduced into college admissions. However, computational methods can also shed light on potential issues of fairness in the essays. For example, Pennebaker et al. found that increased usage of function words (eg. pronouns and articles) and less personal narrative writing was positively correlated with college GPA [34].

3. DATA

The data for this study were 826,624 CAE submitted by applicants to a multi-campus, US public university system. The CAE were written across three academic years: 2015-2016, 2016-2017, and 2017-2018. These CAE were required components of the application, not additional essays submitted for honors programs, scholarships, or anything else peripheral to the main application. For this study, we removed essays that were under 100 characters and/or were

Figure 2: (a) Histogram of student RHI's with quartile boundaries marked. 8420 students with RHI >\$350k not included in plot (but included in this study). (b) Proportion of essays written for each prompt by income quartile. (c) Frequency of word usages from different subsets of the Google Analogy Test Set by income quartile. Each frequency is compared to the global mean. Total refers to all of the words in the dataset.

written by students who did not report their household income. After this filtering step, 812,020 essays remained.

3.1 Reported Household Income

A variety of metadata about each applicant and document were included as part of the dataset, but this study focuses on the reported household income (RHI) provided by each applicant. It is important to note that RHI is not an objective measure of a family's household income. When students are accepted to a university, they provide any pertinent information and documentation (such as tax return forms, W-2, etc.). However, when the application is under review before any official admission decision is made, the only income and wealth information available to a reader is the RHI.

RHI was chosen as the variable of interest for several reasons. First, language variation along class and income lines has been well established in sociolinguistic literature [5, 29]. Splitting by quartile is also a relatively crude metric, and if qualitatively and quantitatively different results emerge in the vectors across quartiles then the problem could be both fundamental and grave. For example, we might expect that the top and bottom quartile have noticeable, measurable differences, but we would not expect the second and third quartiles to be substantively different. Finally, if there are correlations between CAE and income similar to other components of the application and income, new approaches and understanding of fairness and college admissions should be considered, as well as the role of CAE in decision-making. This would push ML fairness research in college admissions to think carefully and critically about data and outcomes, as language variation is not as neat as racial or gender parity but almost always arises.

In the dataset, the average RHI is \$96,746, the median is \$53,000, and the standard deviation is \$125,000. Figure 2(a) shows distribution of income levels as well as the boundaries between the quartiles.

3.2 Prompt Choice

In 2015-2016, students had to write two personal statements to the same two prompts, meaning every applicant wrote two essays. In 2016-2017 and 2017-2018, students selected four prompts to write for from eight possible choices (70 possible combinations of prompts). The eight prompts were distinct

in theme, and if students from a certain quartile were responding to a prompt or group of prompts at significantly higher rates than students from other quartiles, our analysis could be skewed. However, figure 2(b) demonstrates that there are only mild differences in prompt choice across the income quartiles.

3.3 Word Distribution Variation

One possible source of error in this dataset is the difference in word usage between students of different backgrounds. This is a source of error because word vector training algorithms rely on large sample sizes in order to properly learn the contexts in which a given word appears. Our quartiles contain about 70 million tokens each, which is on the low end for word2vec datasets. This means that the quality of a given vector is very sensitive to that word's frequency within the data, a well-known issue that is an active topic of NLP research [20]. Practically speaking, if the word vectors trained on one quartile are able to solve an analogy that the vectors trained on another quartile fail to solve, then this could be due to the relevant words appearing more often in the first quartile.

Figure 2(c) shows the difference in word frequencies by quartile for three different subsets of the Google Analogy Test Set (GATS) [30]. We find that low income students use words from the analogy task more often overall, but this does not tell the whole story. We find that low income students use "family" words more often than high income students by a large margin, and we find (not too surprisingly) that high income students name foreign currencies more often than low income students by an even larger margin. This means that the vectors trained on the essays of low income students have an advantage on the "family" analogies, while the vectors trained on the high income students have an advantage on the "currency" analogies. We will take these word distribution-based advantages into account when analyzing the results of the analogy task.

4. METHODOLOGY

4.1 Vector Training

As mentioned above, we separately trained one set of word vectors on the writing from each income quartile. We chose to train our vectors using a word2vec Skip-Gram model in order to stay in line with Allen [1] who showed mathemati-

GATS Subset	“Viable” Analogies					“Q1 Advantage” Analogies		
	n	Q1	Q2	Q3	Q4	n	Q1	Q4
Family	420	0.629	0.733	0.702	0.681	348	0.672	0.710
Semantic	2446	0.191	0.222	0.233	0.242	391	0.609	0.645
Syntactic	9553	0.382	0.381	0.407	0.451	3307	0.433	0.488
Total	11999	0.343	0.349	0.372	0.408	3698	0.451	0.505

Table 1: Accuracy of each income quartile’s vectors on different subsets of the Google Analogy Test Set. “Viable” refers to analogies whose words appeared at least once in each training set. “Q1 Advantage” refers to viable analogies whose words appeared more often in Q1 (the essays of the lowest income students) than in Q4 (the essays of the highest income students).

cally that vectors trained in this manner would find analogies that exist in the training data.

We trained vectors of size 100 for 20 epochs using a window size of 5. We made all letters lowercase before training, but did not filter stopwords or punctuation. It is possible that changes to these hyperparameters would change the results of the study, but we feel that these are all reasonable choices given the dataset that we started with.

4.2 Vector Evaluation

For the analogy task, we use the Google Analogy Test Set (GATS) [30], which contains 19544 analogies, 8,869 of which are semantic, and 10,675 of which are syntactic. We consider a set of vectors to have “solved” the analogy “A is to B as C is to D” if the closest vector by cosine similarity to $C - A + B$ is D .

We evaluate our vectors on three similarity datasets, all of which are standard intrinsic evaluation tasks:

1. WS-353 [18] consists of 353 pairs of words along with their similarities rated on a scale from 0 to 10 by 13-16 subjects.
2. MEN [9] consists of 3000 word pairs whose similarities were determined by having subjects make binary comparisons between pairs of words rather than rating similarity directly.
3. SimLex-999 [21] consists of 999 pairs of words whose similarity was rated on a scale from 1 to 7 by 500 subjects. As opposed to the first two sets, SimLex-999 explicitly tries to avoid assigning high similarity scores to pairs of words that are associated but not similar (e.g. “coffee” and “cup”).

We measure similarity task performance using Spearman correlation.

5. RESULTS

5.1 Analogy Results

Table 1 shows the accuracy of each income quartile’s vectors on different subsets of GATS. The “Family” subset (as it is called in the original dataset) contains analogies between pairs of words that differ according to gender (e.g. “husband is to wife as grandpa is to grandma”). We chose to look at this subset in particular because it is the only semantic section of GATS whose words were used frequently by students of all four quartiles. The other semantic sections of

GATS (e.g. identifying currencies and world capitals) contained words used very infrequently by lower RHI students. We also split the entire dataset into semantic relations and syntactic relations. Semantic relations rely on word meaning (including the “Family” subset), while syntactic relations rely on morphological/grammatical differences (e.g. “bad is to worse as big is to bigger”). Finally, “Total” refers to the use of GATS in its entirety.

The first time we performed this experiment, we included all “viable” analogies (presented on the left side of Table 1). A viable analogy is one where all four words appear in each of the four sets of word vectors. With this setup, the Q1 vectors performed worst on all subsets, while the Q4 vectors performed best on all subsets except for “Family.” The difference in performance between Q1 and Q4 is very similar (5-7% of all analogies) between the semantic and syntactic subsets. This indicates that the differences we are observing are not only limited to word meaning, but to word usage as well.

Figure 2(c) shows that low RHI students use the words from GATS more frequently than high RHI students. This indicates that word distribution variation generally favors the lower RHI vectors, meaning that the higher RHI vectors performed better *despite* these variations. However, overall average word usage does not necessarily tell the whole story. It might still be the case, for example, that high RHI students use more of the words in the dataset more frequently than low RHI students. In order to more convincingly deal with the word distribution variation problem, we ran this experiment again, including what we call “Q1 advantage” analogies (presented on the right side of Table 1). An analogy has “Q1 advantage” if it is viable and its words appear more frequently in Q1 than in Q4 (i.e. the words are used more often by low RHI students).

Even when restricting ourselves to “Q1 advantage” analogies, the Q4 vectors outperform the Q1 vectors on each subset of the data, and by margins only slightly smaller than in the first experiment. This convincingly shows that word distribution variation is not to blame for the difference in performance we originally observed, as even when we *only* tested on analogies where Q1 has a word frequency advantage, the Q4 vectors solved far more of the analogies in GATS. This indicates that the observed differences in performance are due to the relationship between the analogies in GATS and the ways in which students of different quartiles use words differently.

Dataset	Q1	Q2	Q3	Q4
WS-353	0.594	0.615	0.619	0.583
MEN	0.592	0.625	0.650	0.666
SimLex-999	0.336	0.344	0.346	0.352

Table 2: Spearman correlation of each income quartile’s vectors on three word similarity tasks. Agreement with “ground truth” scores rises as income rises.

5.2 Similarity Results

Table 2 shows the results of each quartile’s vectors on each of our three word similarity tasks. Performance is reported using Spearman Correlation, although the results looked largely the same using Pearson Correlation. Note that with the exception of WS-353 (the smallest dataset), similarity task performance increased monotonically with income. This indicates that the similarity scores generated for these evaluation tasks are more in line with the way that high income students use language than the way that low income students use language. We did not filter the similarity tasks according to word frequencies, as the overall frequencies of the words in each task were very similar across the four training sets.

5.3 Qualitative Results

Word vectors by their nature pick up on semantic relationships between words [1]. It then follows that the underlying cause of these differences in intrinsic evaluation performance is a difference in word meaning between the RHI quartiles. Word vectors allow us to measure the similarity in meaning between two words in a dataset by using the cosine similarity of those two words’ vectors.

Table 3 shows the words most similar to “money” according to the Q1 and Q4 vectors. We find that while low RHI students are talking about “rent”, “expenses”, and “bills” when they talk about money, the high RHI students are talking about “savings”, “donations”, and their “allowance.”¹ This shows how a student’s experience influences the way they use language. There are probably many other words that demonstrate similar qualitative difference and variation across quartiles, but an exhaustive search through them will be considered for future study. Importantly, human readers would be able to detect the differences between the most similar vectors between Q1 and Q4, even if those differences might be subtle. For both vectors, there are clear connections to money, but the differences in how a high income student writes about money and a low income student writes about money is also clear from our qualitative assessment.

For many scholars, especially sociolinguists, the differences seen in the qualitative results alone would be firm evidence of socio-semantic variation in CAE. Research in education have consistently found that students from different social classes experience and navigate schools differently and therefore rely on different language practices to negotiate their pathways in school [28]. Sociolinguistic variation in education has therefore been widely used to study and under-

¹Though not included in the table, we found that Q2’s words were very similar to Q1’s and Q4’s words were very similar to Q3’s.

Rank	Q1		Q4	
	Word	Similarity	Word	Similarity
1	cash	0.768	funds	0.811
2	funds	0.754	fund	0.771
3	savings	0.724	monies	0.755
4	earnings	0.710	profits	0.744
5	rent	0.709	dollars	0.738
6	payment	0.705	savings	0.724
7	groceries	0.672	donations	0.701
8	expenses	0.669	donate	0.698
9	bills	0.6659	allowance	0.689
10	pay	0.659	goods	0.687

Table 3: Bills vs. Allowance: the words most (cosine) similar to “money” according to the Q1 (low income) and Q2 (high income) word vectors.

stand larger processes of social stratification and inequality. Though our qualitative analysis might not possess the depth of ethnographic research, it could still provide useful insights into how student background and experiences shape their language practices.

6. CONCLUSION

We have found that two standard intrinsic evaluation tasks (similarity and analogy) are biased against the writing of lower income students. Word vectors trained on the writing of lower income students systematically perform worse on similarity and analogy tasks than the vectors trained on the writing of higher income students. These findings do *not* indicate anything about writing quality. Rather, our results indicate that the “ground truth” semantic relationships included in these tasks are not the ground truth for everyone.

If analogies arise naturally in word vectors, then we could view the analogy task as a way of measuring what analogies exist for a given training set. If an analogy does not exist in the vectors of a given quartile, then we might say that the students who wrote those essays do not see those words as analogous. Under this perspective, our results can also serve as a way of quantifying the patterns in word usage between students of different income levels. If these patterns are not considered in large scale text analyses in education, word vectors and the many downstream tasks that use them as input could systematically bias the language practices of students based on their social class.

7. FUTURE WORK

We hope that these techniques will be used to audit other word vector evaluation tasks, both intrinsic and extrinsic. We also hope that there will be more discourse surrounding the fairness of evaluation tasks, especially given the increased use of word vectors in educational contexts. However, more work needs to be done in order to determine whether and how it is possible to debias intrinsic evaluation of word vectors with respect to various social dimensions.

ABSTRACT

Online *Peer Instruction* has become prevalent in many “flipped classroom” settings, yet little work has been done to examine the content students generate in such a learning environment. This study characterizes a dataset generated by an open-source, web-based homework system that prompts students to first answer questions, and then provide explanations of their reasoning. Of particular interest in this dataset, is that students are also prompted to evaluate a subset of peer explanations based on how convincing they are, as part of the Peer Instruction learning script. Since these student “votes” are then used in the selection of what is shown to future learners, we cast this as an instance of *learnersourcing*, a paradigm that presents new research opportunities for the Learning Analytics community. This study characterizes a dataset from one *Peer Instruction* tool, that includes not only the student generated answers and explanations, but this novel “vote” attribute, which aims to capture how convincing each explanation is to other learners. The dataset includes longitudinal observations of student responses over the course of a semester, following groups from three STEM disciplines. The data is made available to interested researchers¹.

Keywords

datasets, learnersourcing, peer instruction

1. INTRODUCTION

The effectiveness of *Peer Instruction* on learning [4] [25] *in-class*, and the success of Intelligent Tutoring Systems and MOOCs *outside* of class, have in part, led to the development of web-based platforms for *asynchronous* Peer Instruction [6][27]. Recently, other similar learning environments have been developed, centred on having students explain their reasoning, and then evaluate the explanations of

their peers[22][5]. The increasing use of this form of online learning exercise implies that a new type of data is being generated, wherein lie opportunities to examine theories of how self-explanation and comparative peer assessment may impact learning.

There are several pragmatic motivations for extending Peer Instruction to out-of class activities. First, when scaling-up *Just-in-Time-Teaching* environments, a web-based platform for asynchronous peer instruction can substantially reduce the time teachers’ spend searching the data to identify student misconceptions. Second, when students are asked to compare answers with peers, they receive a form of immediate feedback on their own explanation. Last, when posting threads and sub-threads to large scale on-line discussions, such as MOOCs, an asynchronous Peer Instruction platform offers a more structured alternative and ties student explanations to an answer choice, allowing for more organized aggregation of ideas [2].

These platforms open new research questions and opportunities for the Educational Data Mining community. First, these systems capture new modalities of data, specifically, the written explanations for answer choices, which acts as proxy data: representing the cognitive reflections elicited in conversations students have with peers during small- group in-class Peer Instruction discussions. Second, these environments introduce challenges common to any platform centred on user generated content: quality control and recommendation. The power of having students generating the explanations to different answer choices, and then rating them, enables scaling up of technologies that facilitate flipped teaching practices[14]. However, once these tools *do* scale, sheer volume requires automatic approaches for filtering out low-quality content. Once filtering is complete, recommendation algorithms need to be in place to most effectively help current students navigate the large volume of content generated by past students, with the ultimate objective of optimizing individual learning gains. Further research is needed on *learnersourced* data sets so as to develop best practices that leverage the effectiveness of student written and ranked explanations for adaptive learning experiences, while avoiding the pitfalls that can lead to the valuable data drowning in noise.

2. OBJECTIVES

¹account required at <https://myDALITE.org/signup>

This paper characterizes a dataset generated inside one on-line platform for asynchronous Peer Instruction, with the aim of identifying the potential research questions and limitations afforded by this novel application. The use of the tool is growing, now reaching over 50 course offerings across at least 5 undergraduate institutions in different science disciplines. The contexts are varied, but the common thread is that instructors are all using the tool as an attempt to increase in-class student engagement with pre-instructional quizzes, and tailoring their lectures based on the free-text explanations students provide for their answers. Thus, the ultimate goal of this study is two-fold:

- introduce a novel source of data to the Educational Data Mining research community, which has the potential to open new lines of inquiry based on the unique “voting” attribute. Students not only write explanations to justify their answer choice to conceptual science questions, but they are asked to choose which of a subset of their peers’ explanations are most convincing.
- identify opportunities and challenges related to the design of platforms that rely on *learnersourced* content, such as choosing the most effective content to foster learning; filtering weak or irrelevant student explanations; categorizing and summarizing student explanations for teacher reporting in large classes.

3. BACKGROUND AND RELATED WORK

3.1 Peer Instruction

The interactive engagement technique most relevant to our work here is Peer Instruction: a method for promoting classroom discussion that has been shown to enhance learning [8]. In this common classroom practice, teachers

1. poll their students on a multiple-choice item, using some form of Audience Response System (e.g. clickers),
2. collect the distribution of answers, and maybe even share back with the students,
3. without revealing the correct answer, prompt students to explain their reasoning for their answer choice to a peer nearby, ideally with someone with a different perspective
4. re-poll the students after the small group discussions.

The platform at the centre of this study facilitates an *asynchronous* version of the above script.

3.2 Comparison-based peer assessment

There are other systems similar in design to asynchronous peer instruction; they differ in that the items prompt for open-ended responses, as opposed to multiple-choice questions. However these systems still include a similar *review*-step after submission of an answer, where students are asked to compare and evaluate the quality of the explanations submitted by peers who had already answered the item.

For example, in the ComPAIR system [22], students first submit their written answer to a prompt. They are then shown pairs of their peers’ answers, prompted first to give feedback to each of the answers in the pair, and then choose

one as the better response. The pairwise comparison at the heart of this tool leverages learners’ inherent ability to make judgments regarding an answer’s quality *relative to another*, to make up for the lack of expertise usually needed to provide useful feedback on content in isolation. JuxtaPeer [5] is a similar system, where the pairwise comparisons are anchored on one object at a time, and have been shown to improve the quality of feedback that peers can provide to one another.

3.3 Explanations Datasets

Two of the most prominent sources of learning analytics datasets are from the ASSISTments platform[15], and PSLC DataShop[19]. They both provide significant contributions to Learning Analytics and Educational Data Mining researchers, by making available a wide variety of data from different on-line learning tools. They include datasets with free text responses, including math hints generated by students in ASSISTments, and student explanations to science questions inside the Andes project (hosted in DataShop).

If casting student explanations as *short arguments* in favour of their answer choice, we can look to the Argumentation Mining research community for sample datasets. For example, a dataset of persuasive student essays that are fully annotated for argumentative relations was recently released [26]. The International Corpus of Learner English[12] is used extensively to model how students make arguments.

Another sign of the growing interest in analyzing student generated text are the Automated Essay Scoring[16] and Automatic Short Answer Scoring [17] competitions hosted on the data science platform, kaggle.com. These datasets are still freely available as well.

To the best of our knowledge, none of the above data sources include all of the defining characteristics that are generated by online Peer Instruction, such as the student’s initial answer choice and explanation, a student’s second answer choice after having reviewed peer explanations, and most importantly, the peer explanation the student found most convincing.

3.4 Learnersourcing explanations

Web-based homework systems are effective because students get immediate feedback as to whether they answered correctly. However, as the number of question items grows, as well as associated answer choices, generating high quality explanations that help different types of learners resolve different sets of misconceptions, is impractical for teachers [14]. Moreover, explanations written by content experts may also suffer from the *expert blind spot*, wherein their high level of familiarity with the subject matter actually might actually make their explanations more difficult to understand to novices [20].

The concept of *learnersourcing* is a sub-type of *crowdsourcing*, wherein domain novices contribute to the human computation workflow as part of their learning process [28]. PeerWise [10] is an environment within which students make their own questions, and share them with peers, along with accompanying solutions. RiPPLE is a tool that follows the same model, but adds an adaptive recommendation engine [18]. The AXIS system [29] prompts students to provide ex-

Thin lens 1

A converging lens causes a real image to project, inverted, onto a screen. If the lower half of the lens is completely covered...

- ☒ A. The top half of the real image is missing
- ☐ B. The lower half of the real image is missing
- ☐ C. The section of the real image that is visible depends on the angle you view the image with
- ☐ D. The full real image does form, but it is dimmer than before
- ☐ E. There will be no image formed on the screen

Rationale*

The light rays from the bottom half of the object would normally end up at top half of real image, but now those are being blocked!

Figure 1: Asynchronous Peer Instruction - Step 1, screenshot of student answering multiple-choice question, and explaining their thinking inside a text box

planations to their answers, rate the explanations of their peers, and then machine learning to curate these to a constantly evolving set of explanations that optimize for promoting student learning. ASSISTments, another widely used learning platform, developed the PeerASSIST plugin [24], which asked students to write explanations to their answer submissions, to be used as hints for future students.

4. MYDALITE: PLATFORM AND DATA

4.1 The Platform

dalite-ng is an open-source project [23] that has been in active development since 2013, and has been used in MOOCs as well as on campus course offerings. myDALITE.org is one instance of this code-base, offered as a hosted service that is free to all teachers and students. It is maintained by a network of learning science researchers and practitioners, whose mission is to promote the uptake of student-centred active learning pedagogical practices. Teachers sign up, author their own questions, and distribute to their students at their discretion. The script for the student completing a question item in *dalite-ng* is:

1. **Question start:** student is presented with a multiple-choice question. They are asked to choose an answer choice and enter a free text response to explain their reasoning.
2. **Question review:** without indicating whether the student chose the correct answer, the tool reflects back to the student their own choice, and the explanation they just entered. They are then prompted to reconsider their answer, by reading the explanations of other students. In the top half of the page, they are shown up to 4 other explanations by students who chose the same answer choice. In the second half of the page, they are then shown up to 4 more explanations to a different answer choice. Students must indicate which is their second answer choice in this re-

Thin lens 1

A converging lens causes a real image to project, inverted, onto a screen. If the lower half of the lens is completely covered...

A. The top half of the real image is missing

B. The lower half of the real image is missing

C. The section of the real image that is visible depends on the angle you view the image with

D. The full real image does form, but it is dimmer than before

E. There will be no image formed on the screen

You answered **A** and gave this rationale:

The light rays from the bottom half of the object would normally end up at top half of real image, but now those are being blocked!

Consider the problem again, noting the rationales below that have been provided by other students. They may, or may not, cause you to reconsider your answer. Read them and select your final answer.

- A. ☐ The image is inverted therefore the top half of the original image is on the bottom half of the image formed on the screen. If we cover the bottom half of the screen we cannot see the top half of the original image.
- ☒ B. Since the image is inverted, the bottom part that is covered would have been placed at the top. And since it is covered, that part will be missing in the final image.
- ☐ C. The bottom rays will not pass through the lens, but the top rays will. Since the final real image is inverted, then only the bottom part of the image will be present (representing the top part of the object).
- ☐ D. By blocking the lower half of the lens, you block the rays that end up forming the top half of the image (note that the image is inverted!); therefore the top half will be missing
- ☐ E. I stick with my own rationale.

- D. ☐ Clearly not all rays will hit the screen, but enough rays emerging from all of the object WILL hit the screen. The final real image will be complete, but will be less bright (hence dimmer) because not all of the light intensity goes through the lens
- ☐ The image will still form however it will be dimmer than the original if was covered since there would be more light coming in if there was nothing covering it
- ☐ by covering the lens you only dim down the image you are not decreasing the actual object itself
- ☐ the light image wont be as bright since it escapes a little around the lenses

Figure 2: Asynchronous Peer Instruction - Step 2 , screenshot of student choosing a peer's explanation of a different answerchoice

view step, by selecting one of these explanations. They also have the option of selecting their own explanation as the most convincing. There are several factors that go into the selection of what the students are shown here:

- if the student answered incorrectly on the first step, the explanations in the second half of the page will be for the correct choice
 - if the student did in fact answer correctly on the first step, the explanations in the second half of the page will be for the most popular incorrect answer.
 - There are two different heuristics for the selection of explanations for each answer choice:
 - Random, which is useful for when a question is newly introduced to the database, and not enough students have answered to reliably estimate which answers are most *convincing*
 - preferentially selecting from explanations that have already been chosen as convincing
3. **Question summary** The entire flow of information is reflected back to the student for review: their first answer, their own explanation, their second answer

choice and the associated explanation that they chose as most convincing. The correct answer is also finally revealed.

4.2 Data Collection

The data in this study comes from the 2018-2019 academic year, wherein the platform was more heavily used than ever before, due to additional on-boarding support offered to teachers by the host network. All teachers who make question items on the platform must release their content under Creative Commons licenses, and are made aware that the learning-data generated by the students in their groups may be used for academic research. Students are advised upon signing in, that their learning traces, in anonymized form, may be used for research, and that if they do not wish to share their data, they can revoke their consent at any time, without any impact on academic standing in their courses. The data gathered for this study spans three STEM disciplines where there happened to be the most activity: Biology, Chemistry, and Physics. There are many different groups of students in Physics and Chemistry, each with a different teacher (although all in undergraduate level courses), while all of the data in Biology comes from one large freshman group that used the tool very heavily. In the case of a few groups, the items were assigned by teachers as optional, not-for-credit items, meant to provide extra practice study exercises (this information is provided in the meta-data file of the dataset). For those cases when myDALITE was used for credit, students received 0.5 marks for choosing the correct answer on their first attempt, and 0.5 marks for choosing the correct answer choice after the review step. No credit was ever assigned based on a formal expert evaluation of the student explanations.

4.3 Dataset

Each record in the dataset is comprised of the following fields:

- anonymized student identifier
- anonymized group/course identifier (with meta-data on whether the activities were assigned for credit or not)
- question prompt text (and any associated images)
- student's first answer choice
- student's explanation for their first answer choice
- peer explanations shown to student on second step
- student's second answer choice
- the peer explanation they selected as most convincing for their second answer choice
- timestamps associated with
 - when the student first opened the problem
 - when the student entered their first answer choice, and associated explanation
 - when the student entered their second answer choice, and associated peer explanation

Certain filters were applied for the purposes of data extraction for this study. The only groups that were retained were those having 10 students or more, each of whom having answered at least 10 questions. The only disciplines that were included in the current dataset were ones with over 10,000 student responses.

Table 1: Size of dataset across disciplines

	N_g	N	N_q	N_a	\overline{N}_a
Biology	1	346	232	19653	57
Physics	16	1250	572	50286	40
Chemistry	16	1055	532	28319	27

Table 2: Relative number of answer transitions, from step 1 to step 2

	$1^{st}C$	Δ			Δe
		\sum	$r \rightarrow w$	$w \rightarrow r$	
Biology	0.70	0.10	0.01	0.09	0.40
Physics	0.79	0.09	0.01	0.07	0.44
Chemistry	0.69	0.12	0.01	0.11	0.38

5. DESCRIPTIVE STATISTICS

As can be seen in Table 1, there are relatively similar numbers of responses across the three disciplines.

- N_g : number of groups
- N : number of unique students
- N_q : number of items
- N_a : total number of answers by all students
- \overline{N}_a : average number of items completed by each student

This table demonstrates the valuable longitudinal nature of the dataset, in that across the disciplines, there are, on average, more than 25 observations per student, which could help building a more robust learner models.

In Table 2, we see the proportion of times students changed their answers on the answer review step.

- $1^{st}C$: fraction of responses where students chose the correct answer choice on their first attempt
- Δ : fraction of responses where students switch their answer choice on review step
 - \sum : total fraction of answers where students changed their answer choice from step 1 to step 2
 - $r \rightarrow w$: fraction of responses where students switch their answer choice on review step, going from right to wrong
 - $w \rightarrow r$: fraction of responses where students switch their answer choice on review step, going from wrong to right, presumably after reading their peers' explanations
- Δe : fraction of responses when students do not change their answer choice on review step, but choose an explanation other than their own as most convincing

Across the disciplines, the items in this dataset are easy enough for students to choose the correct answer choice on their first attempt almost three out of four times. The explanations of their peers are almost never able these convince students to switch from the right answer choice to a wrong one. However of the students who choose the wrong answer on their first attempt, after having access to the explanation of their peers, these students switch to the correct answer choice at the review step almost one out of three times. These

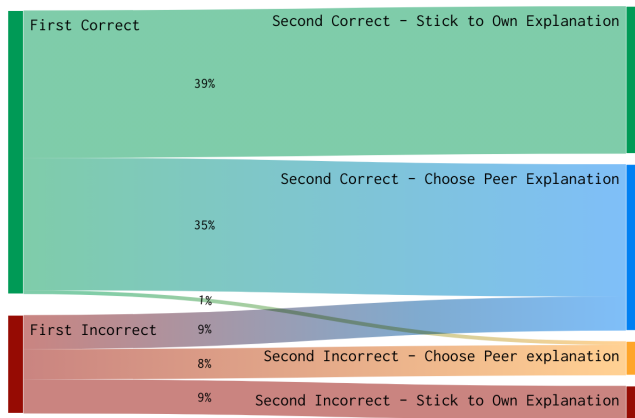

Figure 3: Visualizing student transitions in asynchronous peer instruction with a Sankey diagram

Table 3: Descriptive statistics on explanation word counts

	\overline{WC}	$WC < 5$	$\Delta e_{\text{longest}}$
Biology	7	0.63	0.19
Physics	15	0.42	0.23
Chemistry	19	0.19	0.18

relative transitions are visualized in the Sankey diagram in Figure 3.

In table 3,

- \overline{WC} is the average word count of the explanations
- $WC < 5$ is the proportion of explanations that have less than 5 words
- $\Delta e_{\text{longest}}$ the proportion of times students selected the peer explanation that had the most words amongst those that they were shown.

Here in Table 3, we see that many students write explanations that are too short to form a sentence in the Biology subset, and that even in the other disciplines, the explanations are not long-form persuasive essays, but likely closer to short answers. However, students seem to show a preference for explanations that are longer in length when “voting” for the most convincing explanation on the review step.

6. DISCUSSION

Learnersourcing shows immense potential for scaling up online Peer Instruction, but also presents new challenges common to contexts centred on user-generated content.

A quick sampling of the large number of explanations with less than 5 words likely indicates that students do not see the value of writing explanations, unless they will receive course credit for the task. Work from the argument mining community may be useful here to automatically assess the quality of explanations. Under study is the impact of web-based reputation systems on increasing student engagement, which have been shown to increase engagement in learning environments by offering virtual achievement rewards,

such as badges and leaderboards[9]. Another open research question is in automatic quality control, given that the first few students who complete a question, and submit an explanation, will have their work shown to many subsequent students. Work that has been done on automatic filtering [11] of explanations based on unsupervised clustering could prove beneficial here.

The value and uniqueness of this dataset remains in the “voting” data: modelling what linguistic properties and conceptual constructs students find convincing, in the language of their peers, is fertile ground for research. The longitudinal data also allows for modelling the evolution of how students start integrating domain specific concepts into their explanations across a semester, as well as “voting” for them in the peer-explanations they find most convincing.

6.1 Future Work

Work must now be done on better understanding how to optimize the heuristics that select what peer explanations are shown to students in order to enhance learning. This will require building student models of ability and models of item difficulty. The linguistic properties are also of key interest: can this mode of comparative peer assessment data be used to inform our models of whether students have attained domain literacy? Finally, how do such environments promote student engagement in *flipped classroom* contexts? We look forward to collaborating with the community through this novel source of data to along these lines of research.

Many of the design/implementation decisions for these platforms are made with pragmatic motivations in mind and need to be better informed by learning analytics theory. The platform at the center of this study is a model to examine more closely also because it is an open-source project, developed as part of Research Practice Partnership [7], where learning analytics researchers are actively working with instructors using the tool to better align teaching practices with sound pedagogical design.

7. ACKNOWLEDGMENTS

Funding for the development of myDALITE.org is made possible by *Entente-Canada-Quebec* program, and the *Ministère de l’Éducation et Enseignement Supérieure du Québec*. Funding for this research was made possible by the support of the Canadian Social Sciences and Humanities Research Council *Insight* Grant. Special thanks to Dr. Jonathon Sumner for help with data visualization. This project would not have been possible without the SALTISE/S4 network of researcher practitioners, and the students using myDALITE.org who consented to share their learning traces with the research community.

ABSTRACT

Despite several advantages of online education, lack of effective student-instructor interaction, especially when students need timely help, poses significant pedagogical challenges. Motivated by this, we address the problems of automatically identifying posts that express confusion or urgency from Massive Open Online Course (MOOC) forums. To this end, we first investigate the extent to which the tasks of confusion detection and urgency detection are correlated so as to explore the possibility of utilizing a multitasking set-up. We then propose two LSTM-based multitask learning frameworks to leverage shared information and transfer knowledge across these related tasks. Our experiments demonstrate that the approaches improve over single-task models. Our best-performing model is especially useful in identifying posts that express both confusion and urgency, which can be of particular relevance for forum curation.

1. INTRODUCTION

Massive online courses have changed the academic landscape of today, offering convenient alternatives to learners at significantly reduced costs, compared to traditional educational institutions. With more than six million students taking at least one online course as part of their degree program [16], online education has already become one of the most popular higher education supplements.

Despite several advantages associated with online education, such as diversity of programs, lower cost, and more flexible learning environment, factors such as lack of personalization and low instructor-student ratio pose significant challenges to this learning environment. For the most part, discussion forums continue to be the sole platform for student interaction with others (students and instructors), where learners share their ideas, opinions, or even express their concerns and questions about the course material. Unfortunately, in a typical online class, these forums can quickly get difficult

to manage with few instructors and several learners getting involved and posting their concerns. This situation can hamper the instructors' ability to gauge students' comprehension of course materials and address students' concerns in a timely manner, ultimately reducing learning effectiveness for students.

One way of bringing about the much needed immediacy is by way of automatic curation of the forums, where posts related to confusion about the course material, or those that raise urgent issues are automatically identified. For instance, identifying posts that express confusion (*Confusion Detection*) could help instructors in adapting their teaching strategies during the course by employing more examples, altering the course syllabus or slowing down the pace of instruction. Likewise, automatically identifying urgent posts, i.e. posts which need an immediate response (*Urgency Detection*) and resolving them in a timely manner is important for keeping students engaged. The two types of posts are related but different in the sense that posts that express confusion seek help about the content of the course material while posts that express urgency also seek help but not necessarily directly about the course content. Nevertheless, the ultimate goal of both types of posts is to seek help from others and so there is promise in designing methods that can learn them simultaneously in a multi-tasking set-up.

While previous works have focused on addressing a single forum curation task [1, 20, 21, 22], other studies [24, 25] have also shown that learning features that help address one task may be gainfully used for other tasks—an aspect central to a multi-task learning framework. Another reason for exploring multi-task learning in this domain is the limited availability of labeled data. The use of supervised machine learning approaches requires labeled data annotated by experts, which can be time-consuming, costly, and difficult to obtain in this domain. Unlike single-task frameworks which often suffer from insufficient annotated data, the proposed multi-task framework can share information between related tasks leveraging beneficial information, thus avoiding the need to have large amount of labeled data for individual tasks. However, this comes at the cost of increased model-parameters, which can instead hurt the model. Also, if the jointly learned tasks are weakly correlated, it might be more fruitful to focus on one task at a time since multi-tasking might introduce more noise than useful signals. Despite these issues,

Faeze Brahman, Nikhil Varghese, Suma Bhat and Snigdha Chaturvedi "Effective Forum Curation via Multi-task Learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 356 - 363

the potential gains via an implicit increase in the sample size for training our model by making it learn related tasks has the promise of averaging the noise of each task and thus improving generalization.

In this paper, we propose two multi-task learning architectures, namely Shared-BiLSTM and Specific-Shared Multi-Task, based on Long Short Term Memory (LSTM) networks. Our goal is to use these architectures for forum curation by jointly learning the tasks of Confusion detection and Urgency detection. To investigate the potential promise of our approaches, in light of the concerns mentioned above, we design experiments to answer the following research questions:

RQ1: To what extent are different tasks in this domain correlated?

RQ2: What is an effective multi-task learning architecture for this problem?

RQ3: Can the proposed multi-task learning model leverage the shared signals between the correlated tasks?

RQ4: How does adding more tasks affect the model's performance in the primary tasks?

RQ5: Does an already trained multi-task model help in improving recall in a specific subset of data that could be of particular interest to the instructors? ¹

Our experiments show that automatic forum curation benefits from sharing signals between Confusion and Urgency detection, and our proposed multi-task learning architecture improves on the individual tasks by learning shared and mutually beneficial features between the tasks. We summarize our contributions as follows:

- We empirically explore the extent to which confusion and urgency detection are correlated using representative MOOC forum posts.
- We propose two multi-task learning architectures that share information between related tasks.
- Using representative forum posts, we empirically demonstrate that multi-task models improve over single-task models. Our proposed model is especially useful in detecting posts that express both confusion and urgency, which can be particularly relevant for forum curation.

2. RELATED WORK

As MOOCs have attracted millions of users worldwide, analyzing big data from online courses have become an indispensable means towards understanding students' learning patterns. In this regard, previous research has proposed models to predict dropout or success [7, 13, 14, 18], to measure the impact of social factors in attrition prediction [15], and to automatically curate discussion forums [2, 3, 4]. For example, Ramesh et al. [14] proposed a latent representation model which could be used to abstract student engagement types and to predict dropouts. Wang et al. [19] adopted a content analysis approach to investigate the relationship between students' cognitive behavior in MOOCs forums and their learning gains. Chaturvedi et al. [4] proposed chain-based models that incorporate meta-data along with course information and content of the posts to identify the posts

¹These are instances where posts are labeled as both Urgent and Confusion.

Figure 1: Single-Task Bidirectional LSTM Model.

that require instructor's attention. Chandrasekaran et al. [3] demonstrated the importance of prior knowledge about forum types in enhancing the predictive performance on the instructor's intervention task. Chandrasekaran et al. [2] proposed a supervised classifier which makes use of an automatic discourse parser for robust instructor intervention prediction.

Previous work has also focused on using behavioral and community-related cues to provide an insight into students' intentions, performances, and comprehension levels [21, 21]. Zeng et al. [22] and Agrawal et al. [1] investigated linguistic features along with structural features (e.g., the number of times a post has been read or the number of up-votes) to detect confusion. As identified by previous works [1, 22], one of the primary challenges in this area, is the lack of labeled instances and previous methods have explored the use of domain adaptation for addressing this challenge [23].

To address the problem of labeled data scarcity and leverage the relatedness between tasks, we propose to use multi-task learning which has been proven to perform well in many NLP tasks that include sequence labeling [5], text classification [10], machine translation [6]. For example, Liu et al. [9] proposed different architectures to control the information flow between shared or specific embedding and LSTM layers for text classification. However, multi-task learning has not been effectively explored for the online education domain. In this paper, we propose two multi-task frameworks to jointly learn related tasks (*confusion* and *urgency* detection) from the shared signals.

3. METHODOLOGY

We first define our task in Section 3.1 and in the following sections, we describe the Single-Task (ST), Shared-BiLSTM, and Specific-Shared Multi-Task (SSMT) models.

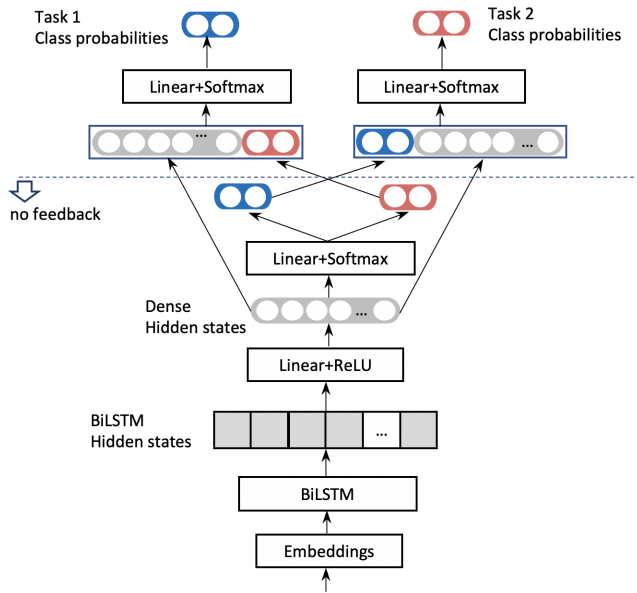

Figure 2: Shared-BiLSTM Model Architecture.

3.1 Problem Formulation

Our training dataset is $D = \{(X^i, Y^i)\}_{i=0}^N$, where X^i represents the i^{th} instance, and $Y^i = \{y_1^i, y_2^i, \dots, y_M^i\}$ denotes a set of M labels for the instance, one corresponding to each task². We assume that each task is a binary classification problem ($y_j^i \in \{0, 1\}$), but the proposed method can also work for multi-class classification tasks. In the following sections, we describe our different architectures.

3.2 Single-Task (ST)

We first create single-task models with identical architectures, to address the individual tasks of detecting confusion and urgency separately. The architecture is depicted in Figure 1. Given a forum post instance as a sequence of tokens $X^i = \{x_1, x_2, \dots, x_T\}$, and the class label Y^i , we first use an embedding layer to get the vector representation of each token x_t , followed by a BiLSTM layer and a linear layer with softmax activation to obtain class probabilities. The model is trained to minimize the cross-entropy loss for each task:

$$L = - \sum_{i=1}^N y^i \log(\hat{y}^i) \quad (1)$$

Where y and \hat{y} are the ground-truth and predicted labels (for a particular task) respectively.

3.3 Shared-BiLSTM

We now describe our first multi-task model that uses a shared BiLSTM encoder between different tasks to capture related information. The shared encoder has its architecture nearly identical to the single-task model except that it has an extra linear layer with ReLU activation between the BiLSTM and the Linear (with softmax) layers. Figure 2 shows the model architecture for two tasks, however; it can be easily extended for M tasks. Note that in this (and the next)

²In our case, we chose $M = 2$, where each label indicates if a post pertains to *confusion* and *urgency*.

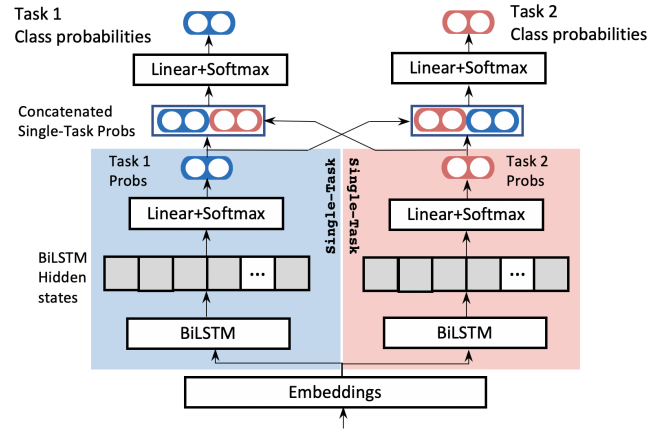

Figure 3: Specific-Shared Multi-Task (SSMT) Model Architecture

figure certain layers are collapsed into one single layer for simplicity. For instance, we depict Linear and Softmax as Linear+Softmax in Figure 2 and 3. We experimented with two main variations of this architecture: (1) Without feedback, and (2) With feedback. The first variation, without feedback, is the part of the model shown below the dotted line in Figure 2. The second variation, with feedback, has the class probabilities of each task concatenated with the dense hidden states (the entire Figure 2). Given the training pairs of a post sequence $X^i = \{x_1, x_2, \dots, x_T\}$, and the class label Y^i , the parameters of the model are updated to minimize total cross-entropy loss for the M tasks:

$$L_{total} = - \sum_{i=1}^N \sum_{j=1}^M y_j^i \log(\hat{y}_j^i) \quad (2)$$

3.4 Specific-Shared Multi-Task (SSMT)

We now describe our second multi-task model, Specific-Shared Multi-Task SSMT, that unlike the Shared BiLSTM model, first models task-specific characteristics and then shares information between the tasks. This model has *task-specific* components, with architectures identical to that of single-task models, to learn task-specific features (shown in highlighted parts of Figure 3)³. Thereafter, the model shares information across tasks by concatenating the predictions of the task-specific components followed by a fully connected layer (with softmax activation) to make predictions for the various tasks. Given the training pairs of post sequence $X^i = \{x_1, x_2, \dots, x_T\}$, and corresponding class labels Y^i , we first trained two separate single-task models, and used them to initialize the *task-specific* components of the multi-task network. We then trained the entire network to minimize the total cross-entropy loss defined in Equation 2. Note that during training, *task-specific* BiLSTM parameters get updated along with other model parameters.

4. EVALUATION

In this section, we evaluate the utility of the proposed multi-task models to address our primary tasks: Confusion and

³Like before, Figure 3 shows the architecture for two tasks, but can be easily extended for more tasks.

Figure 4: Label Distribution for the Stanford MOOC Posts Corpus

Urgency detection. Following previous works, we measure performance using Precision, Recall, and F1 scores of the positive class (*confusion* or *urgency*). This is because from the perspective of forum curation and helping students, positive class is more important than the negative class.

Dataset. We perform our experiments on the Stanford MOOC Posts Corpus [1]. The dataset contains 29,604 anonymized forum posts from 11 Stanford University public online classes spanning three broad domains: Humanities/Sciences, Medicine and Education. While this dataset has several labels, we primarily focus on two labels: Confusion and Urgency, labeled on a scale of 1 – 7. The confusion rating is based on the extent to which the post expresses confusion, such as an inability to understand some concept that is taught in the class. Similarly, the urgency rating is based on how urgent it is that the instructors respond to the post. Although these labels are on a scale of 1 – 7, following previous work [1], we convert these labels to binary values – posts with a score greater than 4 are categorized as *Confusion* (or *Urgency*), and those with a score equal or less than 4 as *Not Confusion* (or *Not Urgency*). Additionally, in some of our experiments, we use an additional label – *Question*, indicating whether the post was a question or not. Figure 4 shows the dataset’s label distribution. We can see that only 15.19% of posts are labeled as *Confusion*, which shows a severe class imbalance in this dataset. We use an 80 – 10 – 10 split for training, validation, and test data.

Training Details. For all our models, we initialized the embedding matrix with pre-trained 100-dimensional GloVe vectors [12]. We use a one-layer BiLSTM network with 80 hidden units. We experimented with using more layers and hidden units. However, that led to over-fitting possibly because of the relatively smaller size of the dataset. We applied dropout [17] of rate 0.2 between the BiLSTM hidden layers and the output layers for regularization, and did not fine-tune the word embeddings during training to avoid over-fitting. Finally, we optimized using the Adam optimizer [8], with a learning rate of 0.001.

Correlation Analysis. We performed inter-label correlation analysis prior to our main experiments. First, we visualize the relationship between Confusion and Urgency (considering the original (1 – 7) Likert scale) in the boxen

plot shown in Figure 5. We can see that there can be disagreement between confusion and urgency labels especially around the threshold rating of 4. For example, there are several posts with confusion rating of 4.5 which would be labeled as *Confusion* but not *Urgency* (because their urgency ratings are less than 4). However, we observe a relatively high correlation between the two tasks for the most part.

Next, we also analyze the Spearman correlation between *confusion* and *urgency* (Table 1). We consider both original as well as the binary labels based on the threshold described earlier. We observe a moderate correlation between Confusion and Urgency (0.570). We also report correlations of these labels with respect to Question to explore whether it can be additionally used in the multi-task setup to improve the performance of Confusion and Urgency detection (the two primary tasks we are interested in). We also find that using binary labels increases the inter-label correlation for all cases. Note that inter-label correlation suggests but does not guarantee or quantify improvement in predictive performance with multi-task learning. Hence, in the following section, we design a new experiment where we consider three single-task models (confusion, urgency, and question) and explore the utility of each to predict Confusion and Urgency (RQ1). We then conduct other experiments to further investigate the utility of multi-tasking for these problems.

Figure 5: Inter-label correlation distribution between ordinal Confusion and Urgency label; the Spearman correlation value is 0.481.

4.1 Experimental Results

In our experiments, we implemented a single-task architecture mentioned in Section 3.2 to create models for each of the three tasks by training them on labeled data from the respective tasks: Single-Task Confusion detection (ST-C), Single-Task Urgency detection (ST-U), and Single-Task Question detection (ST-Q). These form our baselines. We follow a similar naming convention for the Shared-Specific Multi-Task model. For example, we refer to the Shared-Specific Multi-Task model to predict confusion and urgency together as SSMT-CU.

As a preliminary experiment, we compare the performances of our neural Single-Task models with Logistic Regression (LR) using Bag-of-Words and tf-idf features. Comparing the results in Table 2 with those in Rows 1 and 4 of Table 3, we

Labels	Confusion(1-7)	Confusion(1/0)	Urgency(1-7)	Urgency(1/0)	Question(1/0)
Confusion(1-7)	1.0	0.722	0.481	0.545	0.510
Confusion(1/0)	0.722	1.0	0.603	0.570	0.567
Urgency(1-7)	0.481	0.603	1.0	0.852	0.671
Urgency(1/0)	0.545	0.570	0.852	1.0	0.690
Question(1/0)	0.510	0.567	0.671	0.690	1.0

Table 1: Spearman correlation between all labels

Model	Task predicted	F1	Precision	Recall
LR-C+BOW	Confusion	0.45	0.56	0.38
LR-C+tf-idf	Confusion	0.38	0.68	0.27
LR-U+BOW	Urgency	0.61	0.67	0.57
LR-U+tf-idf	Urgency	0.59	0.76	0.48

Table 2: Performance evaluation of single-task models with Logistic Regression as baseline

can see that ST-U and ST-C outperform Logistic Regression based models on both the tasks. So, henceforth we use our neural models for all single task experiments.

RQ1: To what extent are different tasks in this domain correlated?

The goal of our first experiment is to find out if the tasks are correlated enough that model trained on one task can yield reasonable predictive performance on the other task. This would indicate if multi-tasking can help for jointly learning these tasks. For this purpose, we first evaluate ST-C, ST-U, and ST-Q on the task of confusion detection. Even though ST-U and ST-Q were not trained on this label (confusion), we posit that since the tasks of urgency and question detection are correlated with that of confusion detection, these models could have learned signals commonly shared with the confusion detection task. We perform a similar experiment to find correlations with urgency detection. All results are reported in Table 3.

The experiment indicates that the strongest correlation exists between the primary tasks: Confusion and Urgency detection. When used to predict the confusion label, ST-U obtains an F1 score of 0.47, which is only slightly lower than that obtained by ST-C (0.50). Similarly, ST-C performs relatively well in the urgency detection task suggesting that ST-U and ST-C have learned mutually beneficial signals, and can be used in a multi-task setup.

On the other hand, according to row 3 of Table 3, ST-Q has not learn enough mutually beneficial signals for the confusion detection task, suggesting that confusion and urgency are more useful for each other than question.

RQ2: What is an effective multi-task learning architecture for this problem?

We experimented with various versions of the two multi-tasking architectures proposed in Section 3. Here, we summarize these architectures and their performances.

For the Shared-BiLSTM model, we consider a variation without feedback (see Section 3.3) and three others with feedback. For the variations with feedback, we experimented

Model	Task predicted	F1	Precision	Recall
ST-C	Confusion	0.50	0.68	0.40
ST-U	Confusion	0.47	0.46	0.48
ST-Q	Confusion	0.32	0.39	0.27
ST-U	Urgency	0.67	0.72	0.62
ST-C	Urgency	0.44	0.67	0.33
ST-Q	Urgency	0.44	0.60	0.47

Table 3: Performance evaluation of single-task models when used to predict *Confusion* or *Urgency*

with (1) Initializing the entire network randomly, (2) Pre-training and then freezing the shared encoder, and (3) Pre-training the shared encoder but further tuning the entire model to minimize total loss. Together these make up a total of 4 variations of the Shared-BiLSTM model. The performances are reported in the top half of Table 4. We can see that the variations which performed the best are the one that includes feedback with random initialization and the one with feedback, pre-training and freezing.

We also experimented three variations of SSMT: (1) Adding an extra Linear layer with ReLU activation between BiLSTM and final Linear Layers, (2) Including single-task losses in Equation 2 when fine-tuning the entire network, and (3) The model described in Section 3.4 without any changes. The results are summarised in lower half of Table 4. We can see that the model without any changes (as described in Section 3.4) outperforms its other two variations as well as all variations of the Shared-BiLSTM architecture. For the rest of our experiments we use SSMT as our final multi-task setup and we discuss its performance in the rest of the research questions.

RQ3: Can the Specific-Shared Multi-Task model leverage the shared signals between the correlated tasks?

We evaluate our Specific-Shared Multi-Task model for predicting Confusion and Urgency (SSMT-CU). Table 5 shows that SSMT-CU outperforms both ST-C and ST-U on the two primary tasks. Comparing Rows 1 and 3, there is an increase in F1 score for the confusion detection task from 0.50 to 0.56. Comparing Rows 4 and 6 shows that we also obtain a boost in F1 score of the urgency detection task from 0.67 to 0.69. These results are statistically significant ($p < 0.001$) [11], and indicate that SSMT-CU has learned the shared signals between the two tasks. Also, we see that urgency has helped to identify confusion more than vice versa. This can also be observed in Table 3: the drop in performance when using ST-U instead of ST-C for confusion detection was much smaller than the drop resulting from using ST-C instead of ST-U for urgency detection. This also hints that urgency signals are more useful for confusion detection

	CONFUSION			URGENCY		
	F1	Precision	Recall	F1	Precision	Recall
Shared-BiLSTM (w/o fb)	0.50	0.64	0.41	0.66	0.65	0.68
Shared-BiLSTM (+fbrandom-initialization)	0.53	0.67	0.44	0.63	0.70	0.57
Shared-BiLSTM (+fb+pre-training+freeze)	0.53	0.67	0.43	0.67	0.69	0.66
Shared-BiLSTM (+fb+pre-training+tune)	0.48	0.72	0.35	0.63	0.72	0.57
Specific-Shared Multi-Task (+dense)	0.52	0.62	0.44	0.68	0.66	0.70
Specific-Shared Multi-Task (+st-losses)	0.52	0.66	0.42	0.68	0.70	0.67
Specific-Shared Multi-Task	0.56	0.66	0.49	0.69	0.70	0.69

Table 4: Results of different variations of our two multi-task architectures. We indicate feedback with “fb”, and single-task with “st”. Bold fonts denote best performances among top and bottom halves of the table.

Model	Task predicted	F1	Precision	Recall
ST-C	Confusion	0.50	0.68	0.40
SSMT-CUQ	Confusion	0.52	0.71	0.41
SSMT-CU	Confusion	0.56	0.66	0.49
ST-U	Urgency	0.67	0.72	0.62
SSMT-CUQ	Urgency	0.69	0.71	0.67
SSMT-CU	Urgency	0.69	0.70	0.69

Table 5: Performance evaluation of single-task and multi-task models; MT-CU and SSMT-CUQ outperform ST-C and ST-U in the primary tasks.

than confusion signals for urgency detection.

RQ4: How does adding more tasks affect the model’s performance in the primary tasks?

To investigate if adding the task of Question Detection can supplement the primary tasks, we introduce the SSMT-CUQ model and compare it with the existing models. Comparing Row 1 with 2, and 4 with 5 in Table 5, we find that SSMT-CUQ has a better F1 score than both ST-C and ST-U. This shows that adding an extra task still yields better performance than single-task models for the primary tasks.

To evaluate whether it further enhanced the SSMT-CU model, we compare Rows 2 with 3 and 5 with 6. SSMT-CU obtains a higher F1 score (0.56) than SSMT-CUQ (0.52) for the confusion detection task. We attribute the drop in performance of SSMT-CUQ for the confusion task to the relatively weaker correlation between the question detection and confusion detection tasks (also observed in our earlier experiment when comparing Rows 1 and 3 of Table 3). The introduction of question detection task might have introduced more noise and weakened the shared signals of confusion and urgency.

On the other hand, SSMT-CUQ and SSMT-CU have identical F1 scores (0.69) on the urgency detection task (Rows 5 and 6 of Table 5). Despite question detection being as useful for urgency detection as confusion detection (shown in Table 3), SSMT-CUQ did not improve over SSMT-CU because it might have received similar signals from both confusion detection and question detection tasks.

RQ5: Does an already trained multi-task model help improving recall in an specific subset of data that could be of particular interest to the instructors?

We now turn our attention to a specific subset of our dataset – posts labeled as both urgent as well as expressing confu-

Model	Confusion Recall	Urgency Recall
SSMT-CU	0.59	0.70
ST-C	0.49	-
ST-U	-	0.59

Table 6: Performance evaluation for the subset of confused and urgent posts

sion – for their potential to impact learner satisfaction ⁴. In this experiment, the models are not trained on this subset. Instead, we analyze the performance of the (already trained) multi-task model on this subset. Since all the posts in this subset are labeled as *Confusion* and *Urgency*, any model will have a precision of 1 leading to a less informative F1 score. So, in this experiment, we focus on Recall values. Table 6 shows that the Specific-Shared Multi-Task model significantly outperforms the single-task models in the subset for both confusion and urgency ($p < 0.001$).

These results indicate that by leveraging correlated tasks in the multi-task setting, the SSMT model has learned hidden abstractions which help it to outperform single-task models trained solely on confusion or urgency not just in general, but also in the more important subset of the data.

5. CONCLUSION

In this paper, we hypothesize that inter-label correlation or co-occurrence counts suggest but do not guarantee or quantify improvement in predictive performance with multi-task learning. This prompts us to design several experiments to explore the benefits of multi-task learning for confusion and urgency detection in MOOCs forums. We propose the SSMT model, a multi-task learning framework, to facilitate forum curation. We demonstrate that our proposed model outperforms single-task models consistently across both tasks. The multi-task framework takes advantage of the shared signals to yield not only superior performance in general, but also in the subset of the data that is most important for curation: posts that express both confusion and urgency. Future work can extend multi-task learning to explore its generalization performance across various course offerings. More specifically, it can investigate whether a multi-task learner trained on one course, can be effectively used for prediction in other related courses. In this regard, multi-task-based unsupervised domain adaptation can be applied to jointly learn the source and target course classifiers.

⁴We created this subset from test set of our data.

CSCLRec: Personalized Recommendation of Forum Posts to Support Socio-collaborative Learning

Zhaorui Chen and Carrie DEMMANS EPP

{zhaorui, cdemmansepp}@ualberta.ca

ABSTRACT

Discussion forums are used to support socio-collaborative learning processes among students in online courses. However, complex forum structures and lengthy discourse require that students spend their limited time searching and filtering through posts to find those that are relevant to them rather than spending that time engaged in other meaningful learning activities (i.e., discussion). Moreover, existing adaptive systems do not accommodate individual learner needs in these contexts. In this work, we propose a multi-relational graph-based recommendation approach that mines student interaction logs to address the above problems within discussion-based socio-collaborative online courses. To account for the social aspects of learning, our approach incorporates learner modeling, social network analysis, and natural language processing techniques; it offers tailored recommendations of forum posts for learners with different types of interaction behaviors. In our experiments with small online courses, our approach outperformed competitor approaches in terms of recommendation precision while meeting expectations with respect to diversity and novelty. The results illustrate the proposed algorithm's effectiveness in predicting student preferences, suggesting its potential to increase student participation in discussion-related learning activities.

Keywords

Recommender systems, Discussion forums, Computer-supported collaborative learning, Online learning.

1. INTRODUCTION

Asynchronous online discussion forums are widely used to support online courses in higher education [5, 23, 25]. In these forums, many instructors post discussion topics and encourage students to expand so that knowledge can be co-created and developed through progressive discussion. In such socio-collaborative learning contexts, students' active participation and production of learning resources is essential, as less discussion could result in less sharable knowledge and thus less learning within a course [37, 81]. However, forums' complex thread structure and information-heavy posts tend to have a negative impact on student engagement, because much of their time is spent locating relevant forum posts, rather than focusing on core tasks such as debating, reflecting, and learning from each other [1, 37]. To alleviate this type of information overload problem, deploying recommender systems to recommend posts of interest or content generated by others could be beneficial.

Many recommender systems have been used to support learning across varied domains and contexts. For example, data mining approaches were used to suggest course improvements in learning management systems [33], and a workplace learning support system paired users with knowledgeable peers to enable knowledge sharing processes [8]. More recently, other systems have recommended courses to university students [7, 29, 65].

While these examples show the prior success of recommender systems in educational contexts, few have solved the problem of recommending socio-collaborative learning materials in discussion forums for smaller online courses. To fill this gap, we present a novel graph-based recommender system approach. This approach mines learner interaction data using both modelled learner types and natural language processing techniques that were specifically designed for this application domain of smaller discussion-based socio-collaborative learning environments. In our research, we posed the following question: *How do traditional recommender algorithms and those that incorporate principles from socio-collaborative learning perform when suggesting posts in small online socio-collaborative learning contexts?*

2. Related Work

2.1 Socio-collaborative Learning

Socio-collaborative learning, also known as collaborative learning, refers to a class of learning methods in which learners cooperate in a group, relying on each other, being responsible for each other, and accomplishing a common task together [75]. This approach can be traced back to Vygotsky who pointed out that those who are more able can help others perform better [83]. Piaget claimed that the cognitive conflicts generated during social interaction could help the learner reflect on their original point of view, thus enhancing their understanding [44]. Subsequently, collaborative learning has become a widely used pedagogical theory that is also a target of many online learning environments, where it is called computer-supported collaborative learning (CSCL).

CSCL often occurs through online discussion-based forums [17, 26, 39] where information is transmitted through posts to enable knowledge sharing or co-construction among learners. The systems and mechanisms used to support CSCL are grounded in theories such as knowledge building: a specific knowledge co-construction process that emphasizes the creation of ideas through discussion [70, 71]. Many of the proposed knowledge building principles (e.g., diverse and improvable ideas or symmetric knowledge advancement [69]) provide theoretical support for our research.

2.2 Recommenders for Educational Forums

Most work has focused on supporting question and answer (Q&A) forums in university courses [34], MOOCs [49, 53, 87] or other online educational platforms [41, 80] when recommending forum posts. These systems typically aim to reduce the number of unanswered questions by recommending 1) unanswered questions

Zhaorui Chen and Carrie Demmans Epp "CSCLRec: Personalized Recommendation of Forum Posts to Support Socio-collaborative Learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 364 - 373

to students who are able to answer them, and 2) similar questions that have already been answered to users who are about to ask one.

Using a similar recommender system design in smaller-scale socio-collaborative settings is inappropriate because the contexts differ in terms of size and pedagogical purpose. In contrast to MOOCs, these contexts suffer from both a lack of data and the cold start problem. Different from Q&A forums, developing knowledge sharing processes in discussion forums requires the algorithm support increased connectivity among users to facilitate communication [45]. It is also necessary to include posts containing diverse and novel ideas from students who express different points of view so that they might learn from each other [70].

Few studies have investigated how to deal with these challenges. Those that have depend on a priori domain knowledge (e.g., rules [2] or ontologies [18]) which is time-consuming to obtain and has limited generalizability to unseen cases [43]. Given increases in online course delivery and a desire to support students' socio-emotional development and collaborative learning [3, 24], we need approaches that can be used in the absence of domain expertise.

Many have also argued that CSCL personalization technologies should consider the social [42, 66] and other needs of learners [12, 51, 68, 79]. One study investigated learners' knowledge sharing behaviors in closely-knit communities to generate tailored notifications [45]. The notifications aimed to foster knowledge sharing processes within a learning community composed of different learner types. To extend this idea to the context of a forum post recommender system, we set out to develop recommendation algorithms that also consider learner socio-behavioral patterns and created customized strategies for each behavior pattern.

3. Recommender Algorithm: CSCLRec¹

The target users of this system are students or learners. We will use these terms interchangeably. Our proposed algorithm, CSCLRec, relies on 3 types of data that are available in any educational forum: user interactions with forum posts which we call user-to-post (U2P) interactions; communication between users, such as reading, that we call user-to-user (U2U) interactions; and the textual content of forum posts. Using this data, it recommends posts to learners.

CSCLRec has four modules (see Figure 1): a personalized PageRank graph, a learner interaction profiler that analyzes U2U interactions, a content analyzer, and a post filtering module.

3.1 Personalized PageRank Graph

The core of the system is a modified personalized PageRank (PPR) graph [35]. As shown in Figure 2, the PPR has nodes for users, posts, and hypernyms. A hypernym is a superordinate word whose semantic meaning includes a set of other words. For example, "flower" is the hypernym for "rose" or "daisy". Multiple types of relationships including U2P interactions, inter-user relationships, and posts' relationship with hypernyms are computed by other modules and represented as edges in the graph. The weight of user-to-post edges in the graph is biased by a temporal decay rate. Edges representing U2P interactions in the past have lower weights so that the algorithm can focus on the user's recent interests.

We refer to the user who is receiving the recommendations as the active user. To recommend posts to an active user, the algorithm performs a random walk starting from their user node and its

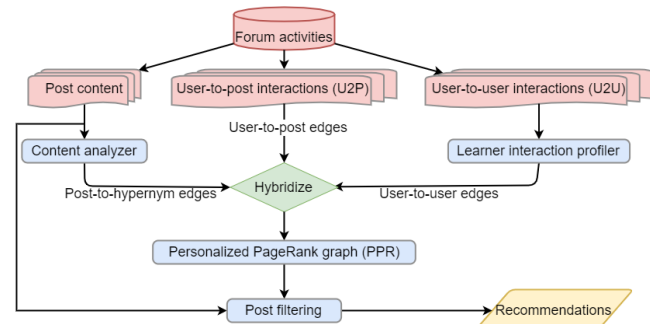

Figure 1. Overall workflow of CSCLRec

connected post nodes. When sufficient iterations have been completed, the nodes' probabilities of being visited by the random walk agent will converge to a steady state. Posts with the highest probability of being visited are presented as the recommendations. We used power iteration [60] to approximate the stationary probabilities and avoid poor computational performance.

3.2 Learner Interaction Profiler
